Received 25 April 2006; revised 8 September 2006; accepted 1 December 2006; published 1 May 2007.

[1] We present high-resolution bulk sedimentary $\delta^{15}\text{N}$ data from the southern edge of the present-day oxygen minimum zone of the eastern South Pacific. The record is interpreted as representing changes in water column nitrogen removal during the last 70,000 years. We found significant fluctuations in the isotopic signal that suggest major reorganizations of the oxygen minimum zone at millennial timescales. These fluctuations were not related to other millennial-scale changes like the Northern Hemisphere's Dansgaard-Oeschger climate swings or local changes in primary productivity, so appear to be dictated by the Southern Hemisphere's climate rhythm. This is preliminarily corroborated by an overall agreement between our $\delta^{15}\text{N}$ data and the sedimentary proxy of ice sheet dynamics in Patagonia, which is in turn correlated with surface water properties at the midlatitude subduction region of the eastern South Pacific intermediate waters. Finally, potential implications on late Quaternary changes in atmospheric CO_2 concentrations are discussed.

1. Introduction

[2] The oxygen minimum zone (OMZ) in the water columns of the Arabian Sea (AS) and the eastern North and South Pacific oceans (ENP; ESP) holds microbial communities that remove reactive or fixed nitrogen (mainly in the form of NO_3^-) from the marine ecosystem. The nitrogen removal (NR) that takes place in these OMZs has the potential of affecting the climate in an indirect fashion, since it partially modulates the total amount of nitrogen available for phytoplankton growth and hence the efficiency of the oceanic carbon sequestration, and directly by the production of the greenhouse gas N_2O . Two decades ago, the estimated global rates of NR were in the order of 100 Tg N yr^{-1} [Codispoti and Christensen, 1985], with a mean residence time for NO_3^- in the ocean of about 10^4 years [Liu, 1979]. This timescale suggested a close link between changes in NR rates and the glacial-interglacial variations in atmospheric CO_2 [McElroy, 1983]. The present

understanding, however, points to a much more dynamic oceanic N cycle, with modern NR rates estimated in the order of $200\text{--}400 \text{ Tg N yr}^{-1}$ and a mean NO_3^- residence time in the order of only $1500\text{--}3000$ years [Brandes and Devol, 2002; Codispoti, 1995; Codispoti et al., 2001]. Therefore millennial-scale variations in the intensity of the NR in the OMZs during the last ice age, like those recorded in the nitrogen isotopic composition in the sediment's organic matter of the AS [Altabet et al., 2002; Suthhof et al., 2001] and the ENP [Behl and Kennett, 1996; Emmer and Thunell, 2000; Thunell and Kepple, 2004], become of interest for climate studies, since they could lead to significant changes in the total amount of reactive nitrogen in the ocean, with potential consequences for the suborbital variability of global primary productivity and the sequestration of CO_2 in the atmosphere [Altabet et al., 2002].

[3] Unlike the broad, orbital-tuned changes in NR that were common to all OMZs at glacial-interglacial timescales [Ganeshram et al., 2000], the shorter millennial-scale variations in NR should reflect the microbiological response to more localized climate forcing, such as regional changes in primary productivity and/or ocean circulation. Therefore millennial-scale variations in NR are expected to show relatively marked differences between basins. Remarkably, the OMZ intensity and NR in the Northern Hemisphere (NH), both in the AS and the ENP, varied synchronously with the millennial-scale Dansgaard/Oeschger abrupt climate shifts that punctuated the NH during the last glacial epoch. This synchronicity was most likely the result of a common NH's climate modulation of local biological productivity and/or local intermediate water ventilation in this two distant areas [Altabet et al., 2002; Behl and Kennett, 1996; Cannariato and Kennett, 1999; Emmer and Thunell, 2000; Hendy et al., 2004; Suthhof et al., 2001]. The effect

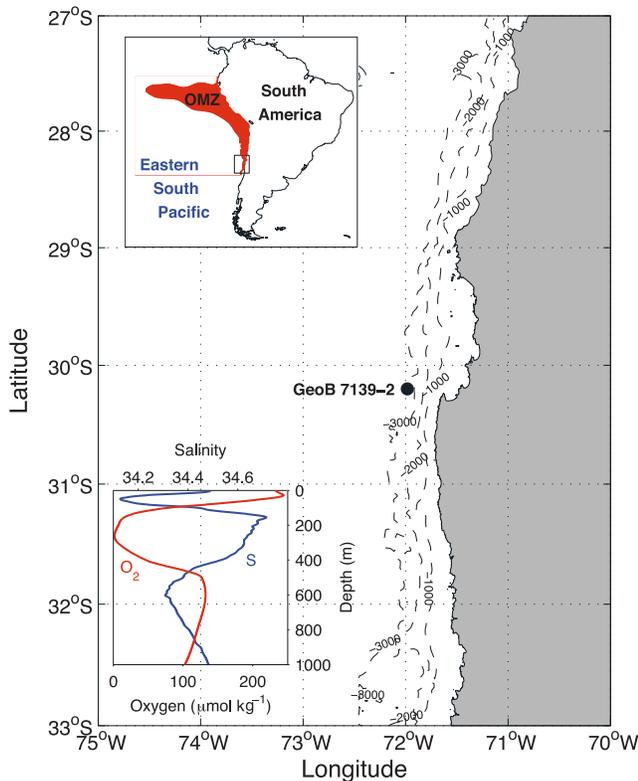

Figure 1. Map of central to northern Chile and the adjacent eastern South Pacific showing the location of the sediment core GeoB 7139-2 ($30^{\circ}12.00'S$; $71^{\circ}58.99'W$; 3267 m water depth). Dashed lines represent the 1000, 2000, and 3000 m isobaths. The core site lies at the southern boundary of the region where O_2 levels drop below $20 \mu M$ as an annual mean (red shaded area in the upper inset). The lower inset shows salinity (solid blue line) and oxygen (solid red line) distributions as a function of water depth at the core site. Note the oxygen-depleted waters (oxygen minimum zone (OMZ)) between 150 and 350 m and the salinity minimum at ~ 100 m.

on global nitrate inventories and greenhouse gas emissions has been highlighted by previous studies, showing that warm interstadial climates were characterized by increased NR rates and therefore probably promoted a weaker biological pump and enhanced nitrous oxide emissions and the opposite during cold stadials [Altabet *et al.*, 2002; Suthhof *et al.*, 2001].

[4] For the Southern Hemisphere (SH) however, there are no comparable high-resolution nitrogen isotope studies focusing on the millennial-scale NR changes during the last glacial period. This is a serious limitation to our understanding of the past nitrogen cycle and its potential role in forcing millennial-scale CO_2 changes in the atmosphere. This limitation rises from the fact that the NR forcing on atmospheric CO_2 changes is a function of the global NR history and not of the NR occurring in one hemisphere only. In addition, we expect that the interhemispheric difference in NR could be particularly critical at the millennial time-

scale, since our present understanding points to a climate asynchrony between both hemispheres during abrupt millennial-scale climate changes [Blunier and Brook, 2001; Stocker, 1998].

[5] On the one hand, the NR in the SH could have been paced by southern, high-latitude climate dynamics, potentially showing “Antarctic type” millennial-scale patterns, as those observed in late Quaternary sea surface temperature [Kaiser *et al.*, 2005; Lamy *et al.*, 2004], and deglacial nitrogen isotope records from the ESP [De Pol-Holz *et al.*, 2006; Higginson and Altabet, 2004]. On the other hand, because of its geographic location, the water column NR in the SH could have varied according to low-latitude millennial-scale climate dynamics, especially to those related with El Niño Southern Oscillation (ENSO)-like configurations in the Equatorial Pacific that appear to be an important mode of NR variability in the modern Pacific realm [Altabet *et al.*, 1999; Codispoti *et al.*, 1988; Codispoti *et al.*, 1986; Morales *et al.*, 1999]. According to recent results based on proxies from the eastern and western sides of the Equatorial Pacific, at millennial timescales, the ENSO-like system resembled Dansgaard-Oeschger or “Greenland type” variability [Koutavas *et al.*, 2002; Stott *et al.*, 2002; Turney *et al.*, 2004]. Thus we have a complex system that can be potentially influenced by various remote-forcing mechanisms, but at the same time, each of them with a distinct type of NH or SH rhythm. Finally, it might also be possible that the NR in the ESP did not respond to remotely forced mechanisms but rather to local processes, such as the oxygen consumption generated by changes in upwelling and its associated biological production [Ganeshram *et al.*, 2000].

[6] Here we present the first high-resolution sedimentary nitrogen isotopes from the southern edge of the OMZ in the ESP that extends to well within the last ice age. Part of this record was the subject of a previous work that discussed in detail the Glacial-Holocene transition of the NR process in the ESP [De Pol-Holz *et al.*, 2006]. Here we extend the record back to 70 ka B. P. and discuss the link between the sedimentary nitrogen-isotope composition and the intensity of the NR in the OMZ. We then try to assess the most probable mechanisms behind the observed variability and the implications for the hypothesis of a global, millennial-scale, water column NR forcing on atmospheric CO_2 .

2. Study Area and Modern Oceanographic Setting

[7] Our study is based on analyses performed on sediment core GeoB 7139-2, which was recovered from the lower continental margin off northern Chile ($30^{\circ}12'S$, $71^{\circ}59'W$; 8.41 m long; 3269 m water depth) during the PUCK expedition onboard the German R/V Sonne in 2001 [Hebbeln *et al.*, 2001] (Figure 1). The core location lies in the realm of the Chile-Peru current system, which extends for almost 40° of latitude as the northward eastern branch of the ESP subtropical gyre. The Chile-Peru current system communicates the surface properties of the northern margin of the Antarctic circumpolar current to lower latitudes. The atmospheric forcing of the current system is characterized

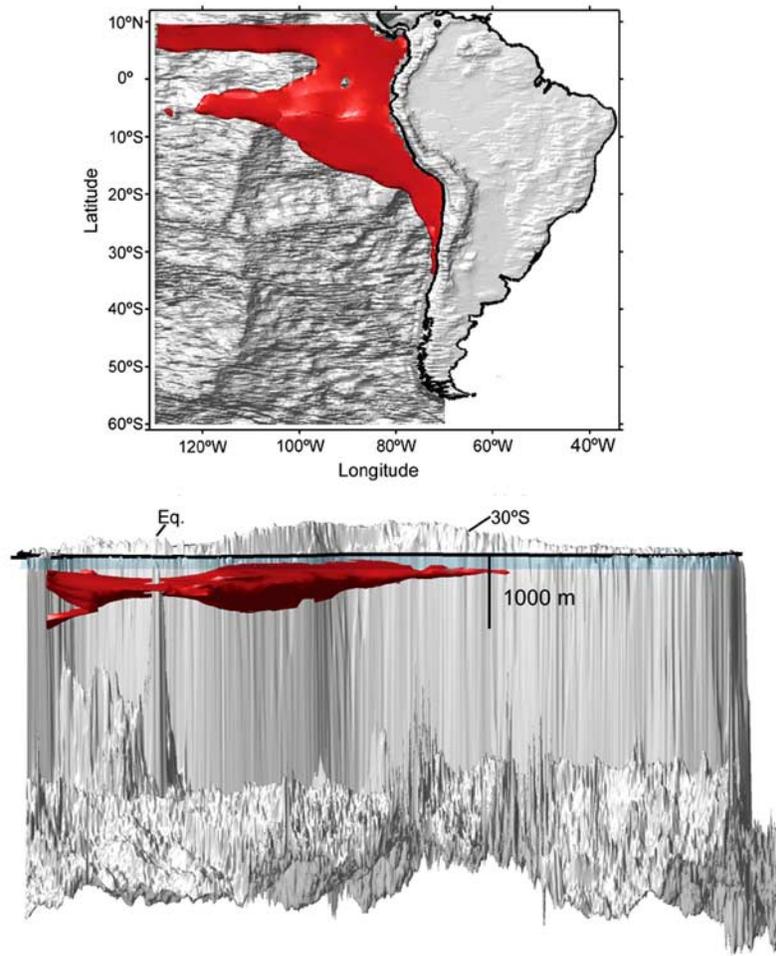

Figure 2. Three-dimensional view of the present-day eastern South Pacific oxygen minimum zone generated using the World Ocean Atlas 1994 climatology data (<http://www.cdc.noaa.gov/cdc/data.nodc.woa94.html>). The red shading encloses the oceanic volume with oxygen contents below 0.5 ml L^{-1} ($\sim 23 \mu\text{mol/kg}$). A smoothed topography is also shown (ETOPO 5). Above-sea-level topography was reduced by a factor of 10 for clarity. The data were downloaded from <http://ingrid.ldeo.columbia.edu/SOURCES>.

by southeasterly winds that promote upwelling and high biological productivity near the coast. The coastal upwelling is driven by the offshore Ekman transport that brings nutrient-rich waters near the surface. The upwelling is a quasi-perennial feature at 30°S , but it can be strongly affected by the El Niño Southern Oscillation (ENSO) [Hormazábal *et al.*, 2001]. Therefore as two of the main constituents of the variability of the Chile-Peru current system are the ACC and ENSO, the core location has the potential to respond to tropical and/or high-latitude forcing [Mohtadi and Hebbeln, 2004].

[8] The surface ocean off Chile around 30°S is occupied by the relatively salty subtropical surface waters (STSW) that characterize the surface of the ESP north of the subtropical front [Tsuchiya and Talley, 1998]. The OMZ (defined here as the volume where the total dissolved oxygen concentration is lower than 0.5 ml L^{-1} or $\sim 23 \mu\text{mol kg}^{-1}$) is a permanent feature in the present-day

study area. Figure 2 shows that the OMZ in the ESP is a large volume of water extending horizontally from the Equator to the extratropical latitude of $\sim 33^\circ\text{S}$ and from the South American coast to 120°W offshore near 5°S , where it is widest. In the vertical, the OMZ occupies the subsurface layer from $\sim 50 \text{ m}$ to 1000 m where it is deepest between 5°S and 10°S . Farther to the south, the OMZ is much narrower in the zonal direction and thinner. Off Chile, the OMZ reaches about $\sim 400\text{--}500 \text{ m}$ depth and the upper boundary frequently intercepts the photic zone during upwelling. Oxygen concentrations drop sharply in the uppermost 100 m of the water column where there is also a distinct salinity gradient (Figure 1). This gradient represents the transition from relatively fresh and recently subducted subantarctic surface waters (SASW)—in the form of eastern South Pacific intermediate water (ESPIW)—to saltier equatorial subsurface waters (ESSW), characterized by higher nutrients and lower oxygen concentrations derived

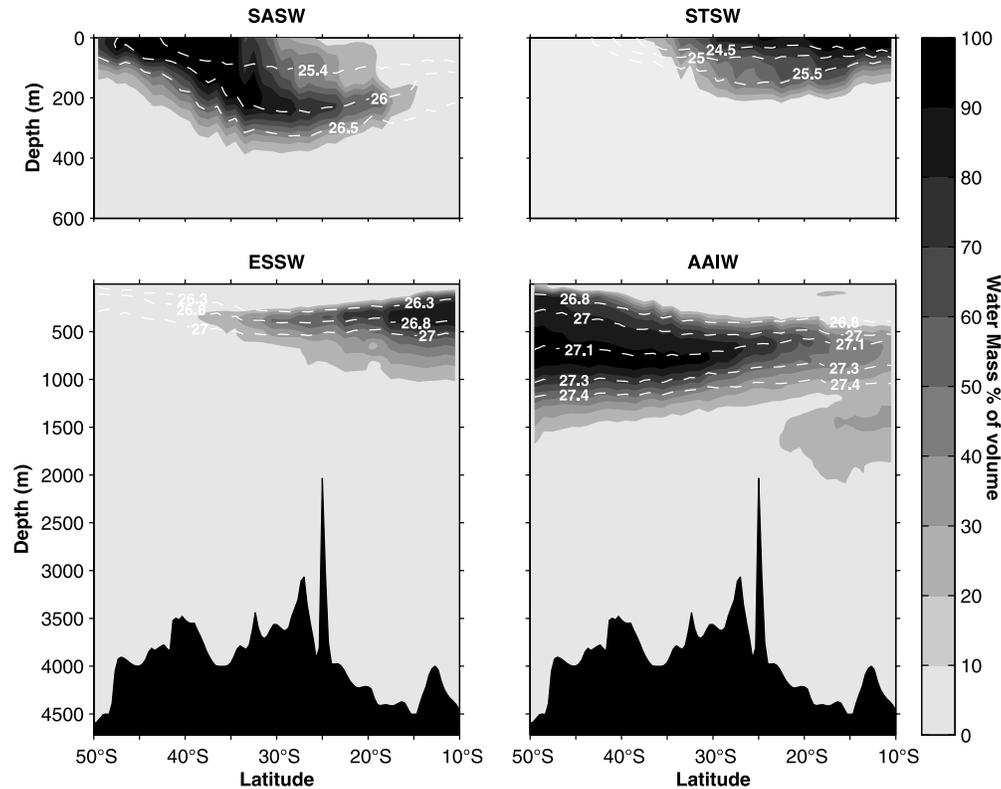

Figure 3. Water mass distribution along a meridional transect from the World Ocean Circulation Experiment (WOCE) line P19 (88°W) [Tsuchiya and Talley, 1998]. The shading gradient represents the relative (%) contribution of a given oceanic volume occupied by a water mass. Results were obtained using the extended optimum multiparameter (OMP) analysis with the source water mass characteristics given in Table 1. (top, left) Subantarctic surface water (SASW) distribution, which after being subducted around 33–40°S, centered at the 26 kg m⁻³ density surface as the eastern South Pacific intermediate water (ESPIW) [Schneider *et al.*, 2003]. (top, right) Subtropical surface water (STSW) distribution. (bottom, left) Equatorial subsurface water (ESSW) distribution. (bottom, right) Antarctic intermediate water distribution. Note that at this longitude (88°W) the Antarctic intermediate water (AAIW) characteristics are almost indistinguishable from those of the subantarctic mode water (SAMW) [Tsuchiya and Talley, 1998]. The data were downloaded from the WOCE-WHP Web site.

from the poleward advection of the OMZ waters by the poleward Peru-Chile undercurrent [Wooster and Gilmartin, 1961]. This situation is analogous to the ENP, where the California undercurrent brings denitrified oxygen-deficient waters toward higher northern latitudes [Castro *et al.*, 2001]. The lower part of the permanent thermocline is occupied by the Antarctic intermediate water (AAIW), which at this side of the Pacific is intimately linked to the subantarctic mode water (SAMW), from which it is derived during winter at far locations of the ESP west of the Drake Passage [McCartney, 1977; Molinelli, 1981; Toggweiler *et al.*, 1991]. The meridional representation of this rather complicated thermocline structure can be constructed by mapping the percentage of a given volume of the ocean occupied by each individual water mass (Figure 3). We have used the extended optimum multiparameter analysis [Karstensen and Tomczak, 1997] applied to high-quality hydrographic data of the World Ocean Circulation Experiment (WOCE) using the source water characteristics given in Table 1.

[9] Figure 3 illustrates that the low-oxygen waters, associated with the ESSW, are advected poleward by the Peru-

Chile undercurrent. The main core of the ESSW lies between the 26.3 and 27.0 kg m⁻³ potential density range (~150–500 m at 88°W), where it reaches as far south as 30°S at 88°W. The latitudinal extent of the ESSW increases toward

Table 1. Source Water Type Characteristics Used During the Optimum Multiparameter Analysis of Water Mass Percentage Contribution

Parameter	STSW ^a	SASW ^b	ESSW ^c	AAIW ^d
Temperature, °C	24	12	10	4.8
Salinity	35.5	34.2	34.8	34.2
Oxygen, μmol kg ⁻¹	215	270	20	280

^bSASW = subantarctic surface water.

^cESSW = equatorial subsurface water.

^dAAIW = Antarctic intermediate water.

the coast where its characteristics can be observed as far south as 40°S. In contrast, the nearby subducted ESPIW is recognized by high-oxygen and low-salinity contents, and according to Figure 3, it ventilates a thin subsurface layer which falls within 25.8–26.3 kg m⁻³ density range. Because of a severe lack of data, the flow path and mechanisms responsible for the thermocline ventilation in the area and the formation and hydrographic characteristics of the ESPIW have been only recently identified [Karstensen, 2004; Schneider *et al.*, 2003]. Briefly, the salinity minimum is attained by a combination of slow mixed layer velocities in the southern, eastward branch of the South Pacific subtropical gyre [Karstensen, 2004] and increasingly higher precipitation regimes near South America [Dávila *et al.*, 2002]. The formation region can be linked to the outcrop of the shallow salinity minimum at the region south of 38°S [Schneider *et al.*, 2003]. It is formed by the process of subduction in the region of negative Ekman pumping velocities over the outcropping density surfaces. During austral winter, the deepening of the mixed layer due to surface cooling and the extension of the 11–13°C temperature band to the outcropping region triggers the subduction and formation of the ESPIW. Similar to what occurs with the AAIW, the ESPIW presently communicates surface properties from the region between the subantarctic and subtropical fronts to lower latitudes, but at shallower depths. Particularly relevant to this study is that today, the ESPIW ventilates a very thin layer of the subtropical ESP above the OMZ (see Figure 1a of Schneider *et al.* [2003] and Figure 3 of this study), where the maximum oxygen concentrations are associated with the salinity minimum (Figure 2, inset). In our opinion, this relationship is a key element related with the past changes of the OMZ, since the water mass configuration shown in Figure 3 was, most likely, very different during glacial times [De Pol-Holz *et al.*, 2006].

3. Material and Methods

3.1. Analysis

[10] Total nitrogen and organic carbon weight percent composition (TN and TOC wt. %) and stable isotope ratios ($\delta^{15}\text{N}$, $\delta^{13}\text{C}_{\text{org}}$, $\delta = (\text{R}_{\text{sample}}/\text{R}_{\text{reference}} - 1) \times 1000$, where R is the ratio of the heavy to light isotope) were measured on the bulk sediments of the gravity core GeoB 7139-2 [Mohtadi and Hebbeln, 2004]. The core was sampled at 1 cm spacing using a “U” channel on the working half of the core. For nitrogen determinations, the sediment was freeze dried and grounded in an agate mortar prior to weighing and subsequent folding in a tin cup. To determine the organic carbon content, the sediment was decalcified adding few droplets of HCl (2N) directly to a silver cup. Each time, 20 to 30 mg of sediment were weighted and combusted in a Thermo Finnigan Flash EA1112 Elemental Analyzer coupled to a Thermo Finnigan Delta Plus Isotope Mass Spectrometer in continuous flow mode via a CONFLO III interface. Normalization to the international $\delta^{15}\text{N}_{\text{Air}}$ and $\delta^{13}\text{C}_{\text{V-PDB}}$ scale was done by running internal laboratory standards (Acetanilide, Atropine and NRC PACS-2) after every fourth sample. Laboratory standards were calibrated against international isotope reference material

(IAEA-N1, IAEA-N2 and IAEA-NO-3; NBS-22, IAEA-CH-6). Isotopic reproducibility was better than $\pm 0.2\%$. All samples were analyzed at the Universidad de Concepción stable isotope facility. Core top $\delta^{15}\text{N}$ measurements in GeoB 7139-2 yielded very similar values to modern surface $\delta^{15}\text{N}$ as measured previously on multicore samples coming from the study area [Hebbeln *et al.*, 2000].

[11] In addition to the TN and TOC sediment weight composition, we have calculated the specific vertical fluxes by way of the $^{230}\text{Th}_{\text{ex}}$ normalization method [Francois *et al.*, 2004] in selected samples. A complete description of the methodology is given elsewhere [Dezileau *et al.*, 2004]. The $^{230}\text{Th}_{\text{ex}}$ normalization permits the separation of the vertical flux component from the total mass accumulation and thus is a robust proxy of local primary production in areas that are subject to sediment redistribution (focusing and winnowing) by bottom currents. Thorium and uranium determinations were made by α spectrometry at the Laboratoire des Sciences du Climat et de l'Environnement, CNRS/CEA, Gif-sur-Yvette, and at the Géosciences Montpellier, Université Montpellier 2, France.

[12] A Finnigan MAT 251 mass spectrometer was used to extend the already published 0–40 ka stable oxygen isotope record of core GeoB 7139-2 [Mohtadi and Hebbeln, 2004]. Following the same procedure, twenty individual tests of the planktonic foraminifera *Neogloboquadrina pachyderma* sin. or *N. pachyderma* dex. ($>150 \mu\text{m}$), depending on abundances, were picked for each measurement. The isotopic composition of the carbonate sample was measured on the CO_2 gas evolved by treatment with phosphoric acid at a constant temperature of 75°C. For all stable oxygen isotope measurements, a working standard (Burgbrohl CO_2 gas) was used, which has been calibrated against the Peedee Belemnite (PDB) by using the National Bureau of Standards (NBS) 18, 19 and 20 standards. Consequently, all $\delta^{18}\text{O}$ data given here are relative to the V-PDB standard. Analytical standard deviation is about $\pm 0.07\%$ (Isotope Laboratory, Department of Geosciences, University of Bremen, Germany).

[13] Spectral analysis was done using the REDFIT program [Schulz and Mudelsee, 2002]. REDFIT was developed to estimate the power spectrum and the red noise from uneven spaced time series, such as most of paleoceanographic records.

3.2. Stratigraphy

[14] The age model of the gravity core GeoB 7139-2 between 0 and 40 ka B. P. is constrained by eight ^{14}C -AMS dating points [Mohtadi and Hebbeln, 2004], which were translated into calendar years using the *CalPal 2004* January calibration curve (<http://www.calpal.de>) using a constant reservoir age of 400 years [De Pol-Holz *et al.*, 2006]. For ages beyond 40 ka B. P. we used the planktonic foraminifera $\delta^{18}\text{O}$ record, in which the presence of the marine isotope stage (MIS) 3.31 (55.5 ka B. P.), the MIS 3/4 boundary (~ 59 ka B. P.), and the MIS 4.2 substage (65 ka B. P.) [Martinson *et al.*, 1987] close to the base of the record, were apparent (Figure 4, top, and Table 2). By extrapolation of the last computed sedimentation rate, the oldest part of the core was estimated to be near 70 ka B. P. Thus the mean

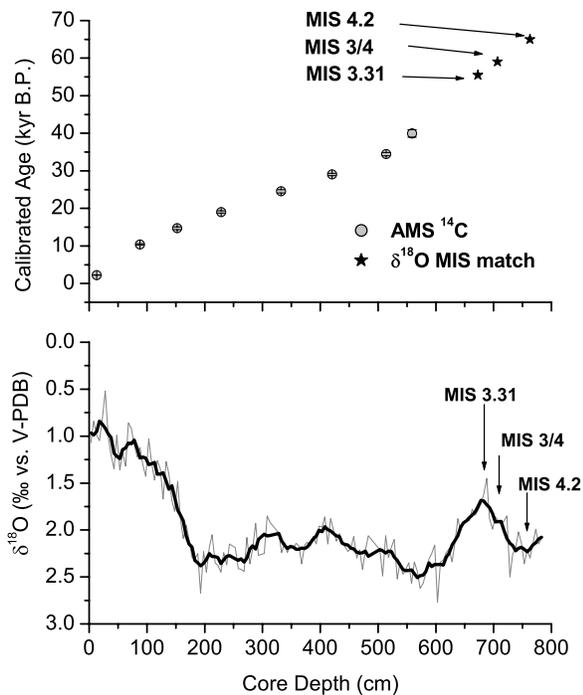

Figure 4. Age model for sediment core GeoB 7139-2. (top) Composite of the age control points: (open circles) calibrated AMS ^{14}C dates with error bars; (solid stars) estimated depths of marine isotope stages 3.11, 3/4, and 4.2; (bottom) $\delta^{18}\text{O}$ curve of the planktic foraminifera *Neoglobobulimina pachyderma* (dex. and sin.) against core depth. The thicker solid line is a 5-point moving average that was used to infer the positions of the marine isotope stage (MIS) 3.11 (55.5 ka B. P.), MIS 3/4 (59 ka B. P.), and MIS 4.2 (65 ka B. P.) [Martinson et al., 1987].

time resolution of the $\delta^{15}\text{N}$ data at the 1-cm interval is ~ 83 years.

4. Results

[15] Our primary proxy data are the nitrogen isotopic composition of bulk organic matter of sediment core GeoB 7139-2. The reconstruction covers the last ~ 70 ka with a mean resolution of ~ 83 years. The $\delta^{15}\text{N}$ values range between minimum values of 6.9‰ near 31 ka B. P., and 13.9‰ at 15 ka B. P. representing the deglacial maximum [De Pol-Holz et al., 2006]. The record shows substantial changes throughout MIS 2 to 4 with a sharp transition from low to high values at the early stages of the deglaciation (Figure 5). The dramatic and abrupt shift in the OMZ intensity at the deglaciation was described and discussed in De Pol-Holz et al. [2006]. During the glacial portion of the record, pronounced $\delta^{15}\text{N}$ minima are found at ~ 17.5 , 25, 31, 45, and 58 ka B. P. with values of ~ 7.5 ‰. Likewise, prominent $\delta^{15}\text{N}$ maxima with values of ~ 9.5 – 11.3 ‰ are found at 29, 36, 56 and 70 ka B. P. The Holocene portion of the record starts with decreasing values after the early deglacial $\delta^{15}\text{N}$ maximum. This trend continues to an inflection point at ~ 7 ka B. P., reaching a minimum value of

10.3‰ to be followed by an increasing trend toward present values of 11.5‰ [De Pol-Holz et al., 2006].

[16] Unlike $\delta^{15}\text{N}$, the $\delta^{13}\text{C}_{\text{org}}$ results vary little throughout the record with values bounded in the range of -20 to -22 ‰ and a mean close to -21 ‰ (Figure 5). The low variability is expressed in a relatively small standard deviation of 0.4‰. There are no clear differences either between glacial and interglacial values or during the MIS 2/3 and 3/4 transitions.

[17] Sedimentary TOC and TN contents are well correlated during the last 70 ka. There exist large differences between MIS 1 and 2 in the TOC and TN contents as well as between MIS 2 and 3 (Figure 5). Lowest values are found during MIS 2, while the Holocene and the late part of MIS 3 (26–32 ka B. P.) show similar relatively high values. TOC and TN contents are relatively steady throughout the early and middle portions of MIS 3. The MIS 4 is characterized by higher TOC and TN contents near 68 ka B.P followed by a progressive decrease to a local minimum at the MIS 3/4 boundary.

[18] The normalization of the TOC content with the ^{230}Th excess method gives us an overall picture of how specific TOC vertical fluxes varied through time avoiding potential flaws, such as sediment redistribution by bottom currents. Overall, the lower resolution Th-normalized TOC fluxes show a similar time evolving structure than the TOC content itself.

5. Interpretation

[19] The interpretation of our downcore $\delta^{15}\text{N}$ record requires an examination of the potential factors affecting the nitrogen isotope composition of the sediments at 30°S and at 3200 m water depth. Among them are: the contributions of isotopically lighter terrestrial-borne organic [Peters et al., 1978; Sweeney and Kaplan, 1980] and inorganic nitrogen [Schubert and Calvert, 2001], changes in the degree of nitrate utilization at the surface by phytoplankton [Altabet and Francois, 1994], isotopic alteration during the particle settling to the ocean floor and during early diagenesis [Haake et al., 2005], and finally, changes in the isotopic composition of the upwelled nitrate.

Table 2. Details on Age Control Points Used to Construct the Age Model of GeoB 7139-2, Chile Margin

Core Depth, cm	^{14}C AMS Age, years B.P.	\pm Error, years	Calibrated Age, calendar years B.P.	Method

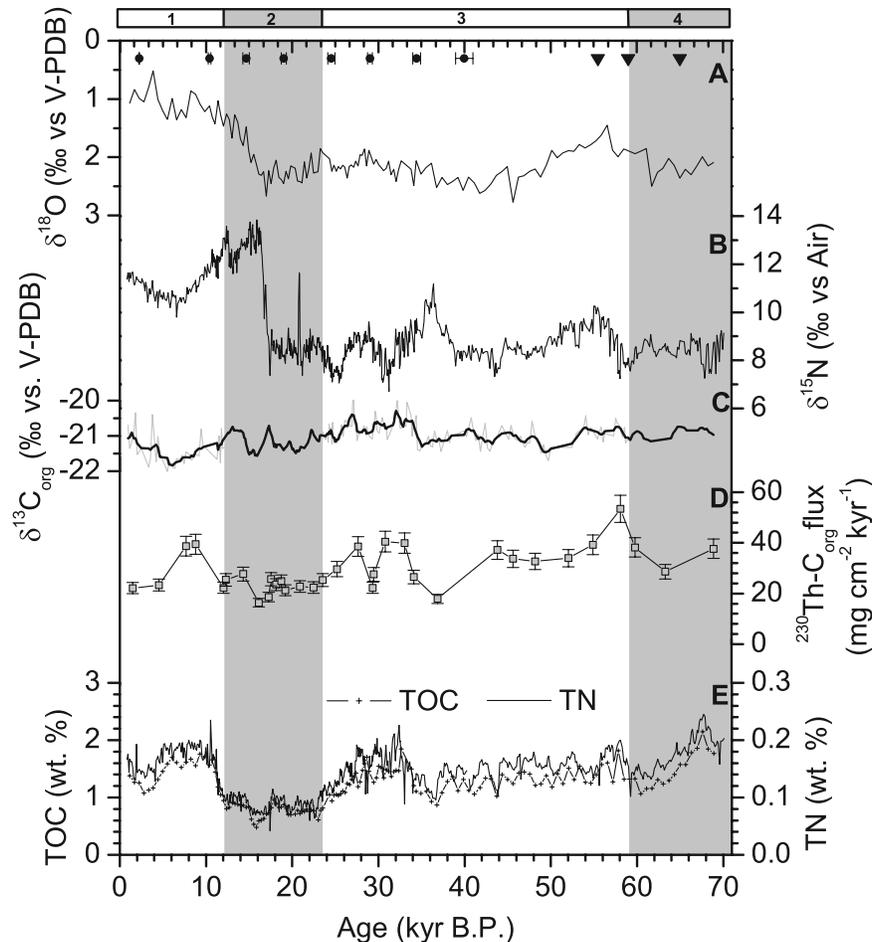

Figure 5. Results from the GeoB 7139-2 sediment core off northern Chile. (a) $\delta^{18}\text{O}$ of the planktic foraminifera *Neogloboquadrina pachyderma* (dex. and sin.); (b) $\delta^{15}\text{N}$ of bulk sediments; (c) $\delta^{13}\text{C}_{\text{org}}$ (thick solid line is a 5-point running mean); (d) ^{230}Th -corrected vertical C_{org} flux (with a 10% error envelope) [Dezileau *et al.*, 2004]; and (e) total organic carbon (TOC) and total nitrogen (TN) weight percent composition of the sediments. Marine isotope stages 1–4 are shaded.

[20] The sediment bulk composition in core GeoB 7139-2 consists mainly of brown olive to light olive clayey silts and silty clays of terrigenous origin and were deposited under hemipelagic processes [Mohtadi and Hebbeln, 2004]. It has been shown that terrestrial organic material is characterized by relatively light $\delta^{15}\text{N}$ values ($\sim 2\text{‰}$ [Sweeney and Kaplan, 1980]) and therefore different admixtures of this material could influence the downcore $\delta^{15}\text{N}$ record. However, the nearby coastal sites in northern Chile are semiarid, with modern precipitation rates of ~ 80 mm year, which promotes desert vegetation (<http://www.meteochile.cl>). We would therefore anticipate a very minor contribution of terrestrial organic matter, at least during arid periods like the late Holocene. For precessional maxima however, like the LGM, the evidence indicates that the area was significantly wetter, with increased river runoff and terrestrial input to the coastal ocean [Dezileau *et al.*, 2004; Lamy *et al.*, 1998a]. Increased precipitation in the area could have promoted a change in the inland vegetation and thus greater contribution of terrestrial organic matter. Despite this, the downcore $\delta^{13}\text{C}_{\text{org}}$ values are in the narrow range of -20 to

-22‰ (Figure 5), which represent typical values for midlatitude marine-borne organic matter [Fontugne and Duplessy, 1981; Rau *et al.*, 1989]. The absence of long-term periodicity or a glacial-interglacial difference in our $\delta^{13}\text{C}_{\text{org}}$ record suggests that, even during the wetter periods, there was no significant influence of terrestrial-derived organic matter in the site and thus we expect negligible alteration of the sedimentary $\delta^{15}\text{N}$ because of this factor.

[21] Inorganic nitrogen adsorbed into clay minerals, particularly onto illite crystals, is known to be present in almost all deep sea samples in varying proportions, and it can sum up to 75% of the total nitrogen content in the sample [Müller, 1977]. Ammonium (NH_4^+) substitutes for K^+ in the interlayer exchange site of illite, with a very constrained isotopic signature that is attained, most likely, on land [Schubert and Calvert, 2001]. Thus downcore $\delta^{15}\text{N}$ measurements on bulk sediments could be altered by different proportions of clay mineral content and mineralogy. Yet surface sediment data from 30°S at a nearby site with similar water depth (GeoB 3368-4) were found to contain 30.5% content of clay minerals of which 17.1% was illite

[Lamy *et al.*, 1998b], thus anticipating only a minor ($\sim 5\%$) contribution from land-derived inorganic nitrogen today in the bulk sedimentary TN. Past variations of this proportion are expected to be minor also, as suggested by downcore variations in the clay mineralogy of a nearby core (27.3°S) [Lamy *et al.*, 1998a]. Furthermore, illite-bond inorganic nitrogen is characterized by a relatively light $\delta^{15}\text{N}$ value of $1\text{--}3\%$ [Schubert and Calvert, 2001], so its presence in larger proportions would tend to decrease the overall high $\delta^{15}\text{N}$ values in our core. However, despite maxima in illite relative content showed a marked precessionality at 27.3°S [Lamy *et al.*, 1998a], $\delta^{15}\text{N}$ minima in our record did not (see below). Therefore we discard the potential effect of inorganic nitrogen isotopic composition in modulating the observed downcore $\delta^{15}\text{N}$ variability.

[22] Another possible factor affecting sedimentary $\delta^{15}\text{N}$ variation involves changes in the degree of nitrate utilization by phytoplankton. Fractionation of nitrogen isotopes during the assimilative reduction of nitrate promotes the enrichment in ^{15}N of the unused pool. If the nitrate residence time in the euphotic zone is sufficiently long, the degree of consumption of nitrate will generate an isotopic signal that will be attained by the newly formed organic particles and that will eventually reach the sea floor. As previously reported [Altabet and Francois, 1994; Farrell *et al.*, 1995; Sigman *et al.*, 1999], the spatial correlation between mean annual surface nitrate content and surface sediment $\delta^{15}\text{N}$ is a consistent feature of the modern Southern Ocean and equatorial Pacific, two areas of the global ocean characterized by high input of upwelled nitrate and incomplete nitrate consumption due to a limitation of biological productivity by iron availability. If this pattern varies with time, it will produce downcore variations in $\delta^{15}\text{N}$ as those reported for the Benguela current system [Holmes *et al.*, 1997]. Although Hebbeln *et al.* [2000] applied this argument as the cause of the large $\delta^{15}\text{N}$ enrichment trend observed in surface sediment samples along the Chilean margin, current data do not support the idea of a significant unused nitrate fraction remaining at the euphotic zone on an annual basis [Conkright *et al.*, 2002]. This is even less likely in a dustier glacial epoch with more iron availability [Ganeshram *et al.*, 2000].

[23] Given the depth of our site (>3200 m), isotopic alterations during the particle sinking and due to early sedimentary diagenesis are expected to operate, as shown in experimental as well as in situ data [Altabet and Francois, 1994; Altabet *et al.*, 1999; Freudenthal *et al.*, 2001; Lehmann *et al.*, 2002]. Besides that experimental evidence has documented both enrichment and depletion of $\delta^{15}\text{N}$ during these processes, it has also highlighted the importance of redox conditions and sedimentation rates as key factors controlling the magnitude of the isotopic effect. More importantly, should these processes or rates vary with time, they may drive downcore variations in the $\delta^{15}\text{N}$ record in a highly unpredictable way [Haake *et al.*, 2005]. In a companion work, we have addressed this issue by showing that there are no significant differences between the surface sediment's and subsurface nitrate's $\delta^{15}\text{N}$ values along the northern and central parts of the Chilean margin (R. De Pol-Holz *et al.*, Controls of sedimentary N isotopes along the Chile margin, submitted to *Deep Sea Research*,

Part II, 2006, hereinafter referred to as De Pol-Holz *et al.*, submitted manuscript, 2006). The absence of a diagenetic imprint was expected because of the relatively high sedimentation rates along the Peru-Chile margin [Muñoz *et al.*, 2004], in line with the findings of Altabet *et al.* [1999] and Francois *et al.* [1997] that showed no isotopic effects on $\delta^{15}\text{N}$ values for areas with moderate to high sedimentation rates. Moreover, because of the depth of the study site, we expect almost unchanged redox conditions for the relatively short time span of our record. Thus we find very unlikely that the downcore $\delta^{15}\text{N}$ variability in our record is due to changing diagenetic effects.

[24] Yet, $\delta^{15}\text{N}$ values throughout the GeoB7139-2 core are significantly higher than the present-day mean oceanic nitrate ($\delta^{15}\text{N}$ of $5\text{--}6\%$ [Sigman *et al.*, 1997]) and considerably higher than sediments from off southern Peru at a similar water depth [Ganeshram *et al.*, 2000]. Having ruling out local effects as the cause for $\delta^{15}\text{N}$ values and variability in our record, we now discuss the effect of the isotopic composition of nitrate that feed the upwelling system of northern and central Chile as the most likely factor controlling both the $\delta^{15}\text{N}$ value today and its variability through time.

[25] The intricate thermocline structure of the ESP (presented in section 2) complicates the evaluation of the potential source of nitrate to our site. As depicted in Figure 3, and assuming that the contribution of the relatively nutrient free STSW is very minor, there are three potential sources of subsurface nitrate for phytoplankton growth at 30°S , namely the northern-sourced ESSW, and the southern-sourced ESPIW and AAIW (SAMW). Consistent with surface data from the Southern Ocean region [Sigman *et al.*, 1999], the nitrate $\delta^{15}\text{N}$ at the core of AAIW in our region is significantly lower (7%) (De Pol-Holz *et al.*, submitted manuscript, 2006) than surface sediment $\delta^{15}\text{N}$ in the region ($\sim 11.5\%$) [Hebbeln *et al.*, 2000]. Therefore, and considering the fact that AAIW occupies a considerable deep layer in the water column, we find that it is unlikely that this water mass could be a significant source of nitrate for upwelling in our study site.

[26] Instead, at shallower depths, the ESPIW's preformed nitrate is theoretically derived from the unused pool of subantarctic surface water that subducts south of the subtropical front [Schneider *et al.*, 2003]. These waters should bear a nitrate $\delta^{15}\text{N}$ signature of $5\text{--}7\%$ when they are part of the Antarctic circumpolar current in the Southern Ocean (north of the subantarctic front) [Sigman *et al.*, 1999]. However, this signature should become progressively heavier as nitrate is advected northward and consumed by phytoplankton along the surface displacement of the Chile-Peru current, especially when it intersects the highly productive upwelling centers off central Chile. This is likely the explanation of the northward enrichment in surface sediment's $\delta^{15}\text{N}$ off southern and central Chile [Hebbeln *et al.*, 2000; De Pol-Holz *et al.*, submitted manuscript, 2006]. However, farther to the north of the subtropical front, once subantarctic waters have subducted in the form of ESPIW, its nitrate concentration becomes extremely low and its N isotopic composition suggest that rather the long-range transport of preformed nutrients from the south, its nitrate content is most likely the result of local processes, i.e., the

regeneration of organic matter and vertical supply from the underlying ESSW (De Pol-Holz et al., submitted manuscript, 2006). Thus although for the present-day situation the ESPIW nitrate $\delta^{15}\text{N}$ would fit within the surface sediment $\delta^{15}\text{N}$ values at our site, we favor the widespread idea that nutrients at our site have their remote origin in the core of the OMZ, in analogy to the California current system [Castro et al., 2001; Liu and Kaplan, 1989]. One implication of our interpretation is that the high value of core top $\delta^{15}\text{N}$ is the direct consequence of the isotopic effect of NR within the OMZ. The first step in the NR pathways (NO_3^- reduction to NO_2^-), is characterized by an important kinetic isotopic fractionation that leaves the unused NO_3^- fraction enriched with the heavy ^{15}N isotope [Cline and Kaplan, 1975]. Vertical transport mechanisms like upwelling and/or mixing will bring the enriched NO_3^- to the photic zone where it is assimilated by phytoplankton, leading to a downward flux of organic matter that carries the NR signal to the ocean floor. When sediment organic matter is well preserved, like in high-accumulation-rate settings, the down core ^{15}N record provides a faithful indication for past changes in water column NR [Altabet et al., 1999], and hence a proxy for the OMZ intensity. Indeed, modern sediment $\delta^{15}\text{N}$ values at our site ($\sim 11.5\%$) [Hebbeln et al., 2000; De Pol-Holz et al., submitted manuscript, 2006] are undistinguishable from nitrate $\delta^{15}\text{N}$ at 200 m (De Pol-Holz et al., submitted manuscript, 2006) where the core of the ESSW is located (Figure 3). Thus in line with several other paleoceanographic studies at different latitudes in the ESP [Agnihotri et al., 2006; De Pol-Holz et al., 2006; Higginson and Altabet, 2004; Martinez et al., 2006; Robinson et al., 2007], we will interpret the GeoB 7139-2 downcore variations in sedimentary $\delta^{15}\text{N}$ as representing the NR history of the subsurface waters at the OMZ.

[27] Our interpretation is consistent with the synchronous early deglacial abrupt 5‰ increase in sedimentary $\delta^{15}\text{N}$ in our site and off Peru [De Pol-Holz et al., 2006; Higginson and Altabet, 2004], which suggests a common origin for the signal. Similarly, the lower glacial $\delta^{15}\text{N}$ values of our core should reflect reduced or even absent NR in the OMZ area as reported for the Peru margin [Ganeshram et al., 2000; Higginson and Altabet, 2004]. Yet, our glacial values are significantly higher (2 to 3‰) than glacial sediments from the OMZ region and that of mean ocean nitrate [Sigman et al., 1997]. This would point to a different source of nutrients at our site during the well-ventilated glacial ESP. We will discuss further the isotopic difference in our record compared from that off Peru when we propose the mechanism responsible for the NR changes in the ESP.

6. Discussion

6.1. Causes of Variability in the OMZ of the ESP at Millennial Timescales

6.1.1. Orbital Forcing or Internal Variability?

[28] The relatively large-amplitude isotopic changes that characterize our record between 20 and 67 ka B. P. lasted for several millennia. The time window between the three major isotopic maxima at 56, 36 and 16.5 ka B. P. may well express an inherent 20 ka cycle in the OMZ intensity

consistent with orbital forcing. A link between precession and $\delta^{15}\text{N}$ in our core can be rationalized by three ways. First, *Dezileau et al.* [2004] found strong agreement between precession and biogenic vertical accumulation rates in a nearby site (27°S). The connection would be established by the increased oxygen demand at times of higher primary productivity during precession maxima [Dezileau et al., 2004]. Second, an important low-frequency modulation of ENSO has been attributed to precession by modeling experiments [Clement et al., 2000]. They show that insolation changes at low latitudes induce variations in the frequency and intensity of ENSO events. Third, the latitudinal position of the oceanic fronts, upwelling centers, low-pressure systems and the southern westerlies has been also shown to vary with precession [Lamy et al., 1998a]. The latitudinal displacement of those characteristics would tend to alter many other oceanographic features; among them, the active formation area of intermediate water masses is relatively important for the ventilation of the OMZ layer [De Pol-Holz et al., 2006]. It is then important to differentiate how much, if any, of the variability of our data originates from orbital forcing or by internal millennial-scale adjustments of the OMZ. For that, we have performed frequency analysis of the GeoB7139-2 $\delta^{15}\text{N}$ record after having extracted the mean in two different subsets, the first between 0 and 16.5 ka B. P. and the second between 17.5 to 67 ka B. P. The goal here was to remove the effect of the large deglacial $\delta^{15}\text{N}$ rise in the frequency analysis, which would tend to assign too much energy to lower frequencies. Results from the frequency fit show that the variability in our $\delta^{15}\text{N}$ record is similar to a theoretical red noise spectrum with a persistence timescale (τ) of 600 years [Mudelsee, 2002] (Figure 6a). However, in our data, there is significantly less spectral power in the 0.2 to 1 cycles/ka frequency range than in a theoretical red noise spectrum (Figure 6a) precluding an optimum statistical fit with a 5% significance level [Schulz and Mudelsee, 2002]. Figure 6a shows that there is a peak in spectral power concentrated near the precessional frequency band (20 to 22 ka period), but without the sufficient amplitude as to overcome the critical “false alarm” level of 99.86% determined for our record [Thomson, 1990]. We will therefore cautiously consider the result of this analysis as an indication that precession was probably not the primary cause of variability for the $\delta^{15}\text{N}$ in the ESP during the last 70 ka B. P. Additionally, we have plotted the resulting $\delta^{15}\text{N}$ record, after the extraction of its mean, together with the January (summer) insolation at 15°S, for visual comparison (Figure 6b). It can be seen that the three $\delta^{15}\text{N}$ incursions separated by ~ 20 ka occur during different phases of the insolation curve. Because of the limited time extension of our data, we cannot statistically resolve the obliquity and eccentricity periods, which seem to have played a major role in the glacial-interglacial NR changes as those observed in the three main OMZs [Ganeshram et al., 2000; Liu et al., 2005]. Also, we cannot rule out that for longer time series, the ~ 20 ka cycle indeed becomes significant. Low $\delta^{15}\text{N}$ values present during precession maxima, for example, may be an indication that, among the mechanisms discussed above, the displacement of oceanic fronts toward lower latitudes promotes a better

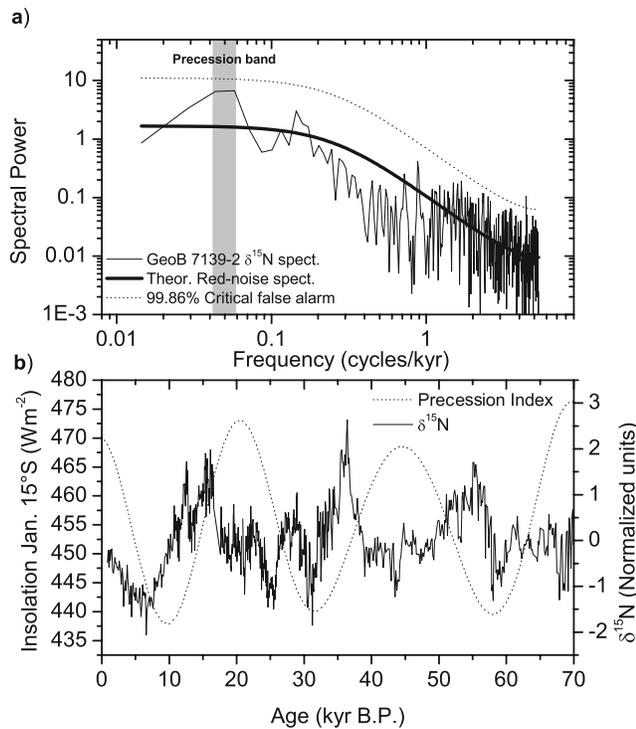

Figure 6. Frequency analysis of the GeoB 7139-2 $\delta^{15}\text{N}$ record and its relation with precession. (a) Bias-corrected spectrum of the $\delta^{15}\text{N}$ time series (thin solid line); theoretical red noise spectrum based on the calculated persistency (thick solid line) and “false alarm” level (99.86%) [Schulz and Mudelsee, 2002]. (b) The resulting GeoB 7139-2 $\delta^{15}\text{N}$ time series after the extraction of the mean (plotted without scale) compared with the January insolation at 15°S (see text for details).

ventilation of the OMZ. We interpret, however, that the $\delta^{15}\text{N}$ maxima documented in our record are the response to intrinsically suborbital phenomena; i.e., internally forced by millennial-scale climate fluctuations.

6.1.2. Productivity Versus Ventilation

[29] Having established that the mode of variability in our $\delta^{15}\text{N}$ record is dictated most likely by millennial-scale dynamics, we need to assess whether this rhythm was set from productivity-derived oxygen consumption or by remotely forced ventilation processes. Millennial-scale changes in NR in the global ocean have been shown to occur by either shifts in local primary production [Altabet *et al.*, 2002; Emmer and Thunell, 2000], or by variations of the physical processes that determine the formation and ventilation of the intermediate waters at their source area [Higginson and Altabet, 2004; Kienast *et al.*, 2002].

[30] For the ESP, the productivity-driven mechanism was proposed by Ganeshram *et al.* [2000] as the most probable forcing behind the glacial-interglacial differences in NR. The idea found support in the covariation between their $\delta^{15}\text{N}$ record and the productivity proxies that they used. More recently, however, Higginson and Altabet, [2004] and De Pol-Holz *et al.* [2006] challenged that argument by the

use of new proxies that showed no relation between productivity and the abrupt rise in $\delta^{15}\text{N}$ at the beginning of the deglaciation. They proposed instead that changes in the ventilation of the intermediate waters were the most likely alternative to explain the glacial-interglacial difference in the $\delta^{15}\text{N}$ records of the ESP, albeit invoking different water masses.

[31] In order to discriminate whether the “biological” or the “physical” mechanism was the main precursor of the millennial-scale NR variations in the ESP during the glacial period, we have compared our $\delta^{15}\text{N}$ record with sedimentary proxies of primary production and ventilation in the ESP. Although the TN or TOC contents of sediments has been commonly used as a proxy for paleoproductivity [Altabet *et al.*, 2002; Ganeshram *et al.*, 2000; Liu *et al.*, 2005], these types of proxies might be affected by dilution processes that can corrupt the productivity signal [Dezileau *et al.*, 2004; Francois *et al.*, 2004]. In order to overcome this problem, we have normalized the biogenic fluxes using the ^{230}Th technique [Francois *et al.*, 2004]. This method permits the estimation of the export productivity, which in turn, should be linked with the oxygen demand in the subsurface ocean and affect the NR rates and $\delta^{15}\text{N}$.

[32] Figure 5 suggested a poor correlation between our productivity proxies and the $\delta^{15}\text{N}$ record. Periods with elevated $\delta^{15}\text{N}$ do not consistently coincide with higher biogenic fluxes. The $\delta^{15}\text{N}$ signal, however, could be more sensitive to changes in the whole area-integrated primary productivity of the ESP, rather than the localized variations of primary productivity that is shown in Figure 5. Unfortunately, until now we do not have a consistent estimate of the whole area-integrated productivity because of the lack of robust records in the ESP system. Thus although we cannot rule out completely the possibility that millennial-scale variability in NR is related to productivity at a regional scale, we will nevertheless examine a potential control of NR by ventilation.

6.1.3. Ventilation of the OMZ: Low- or High-Latitude Control?

[33] There is a clear imbalance between the Northern and Southern hemispheres with respect to the number of studies focusing on millennial-scale climate variability during the last glacial period. While the former has been subject to a wide number of studies, data/observations from the SH are still scarce. Most of what we know about the millennial-scale climate changes in the SH comes from the studies on Antarctic ice cores, which may be representing isolated conditions of Antarctica and not hemisphere-wide features [Moreno *et al.*, 2001]. However, a growing body of evidence shows that the SH’s climate at mid to high latitudes responded also to an “Antarctic” timing [Charles *et al.*, 1996; De Pol-Holz *et al.*, 2006; Kaiser *et al.*, 2005; Lamy *et al.*, 2004; Pahnke and Zahn, 2005; Pahnke *et al.*, 2003]. From this perspective, the location of the GeoB 7139-2 site should be considered adequate for documenting tropical and high-latitude forcing [Mohtadi and Hebbeln, 2004]. Since the core of the OMZ is within the tropical band, we expected ventilation changes associated with the ENSO-like tropical Pacific variability. At millennial timescales, evidence show that ENSO-like variability resembles

Dansgaard/Oeschger events as those recorded in the Greenland ice core records [Koutavas *et al.*, 2002; Stott *et al.*, 2002; Turney *et al.*, 2004]. A connection between an ENSO-like type of variability and the OMZ (expressed as NR intensity) can be expected since during modern El Niño conditions, the thermocline and oxycline depth in the ESP deepen considerably [Morales *et al.*, 1999; Ulloa *et al.*, 2001]; the converse occurs during La Niña conditions. Remotely forced changes in NR intensity have been associated with modern ENSO in the ESP [Codispoti *et al.*, 1988], primarily as a consequence of this vertical displacement and associated reduction of the OMZ's volume [Morales *et al.*, 1999]. Furthermore, those NR changes have been recorded in the $\delta^{15}\text{N}$ of settling particles, as it was the case for the 1991–1992 El Niño event in the ENP [Altabet *et al.*, 1999]. However, our ESP $\delta^{15}\text{N}$ record does not resemble Dansgaard/Oeschger events. As discussed in De Pol-Holz *et al.* [2006], the deglacial portion of the GeoB 7139-2 $\delta^{15}\text{N}$ record was dominated by an “Antarctic” timing, which distinctly differentiated it from analogous millennial-scale records of the NH. Now, we can extend this conclusion further for the glacial during MIS 3 and 4. These results then set a common SH mode for atmospheric temperatures [EPICA Community Members, 2004], sea surface temperatures [Kaiser *et al.*, 2005; Lamy *et al.*, 2004] and OMZ intensity in the ESP during the last 70 ka. The absence of Dansgaard/Oeschger-like patterns in NR intensity in the ESP during MIS 2 to 4 has implications for the role of low-latitude forcing on the OMZ. If during the glacial, the millennial-scale ENSO promoted mean oceanographic conditions similar to the interannual analog, sustained periods of ENSO-like warm phases should have been characterized by a deeper thermocline, reduced trade wind activity and reduced equatorial upwelling, resulting in a reduction of the OMZ volume and NR. The opposite would hold for cold phases. Thus low-latitude control of the ventilation of the OMZ appears to be unlikely, leading us to explore for a high-latitude ventilation control.

[34] High-latitude control of the ventilation of the OMZ during the past should be related to the formation rates and history of thermocline waters like SAMW/AAIW and/or ESPIW. De Pol-Holz *et al.* [2006] showed that the deglacial onset and successive millennial-scale changes of the NR were difficult to explain by assuming that they originating in the Southern Ocean source regions of the SAMW and AAIW. On the contrary, the intermediate waters originated near the subpolar front showed a reinforced ventilation during periods of high NR and vice versa [Bostock *et al.*, 2004; Pahnke and Zahn, 2005; Spero and Lea, 2002]. On this basis, De Pol-Holz *et al.* [2006] hypothesized that the mechanism behind the abrupt shift in $\delta^{15}\text{N}$ was probably linked to the closer midlatitude subduction region of the modern eastern South Pacific intermediate water (ESPIW). Today, this water mass occupies and ventilates a thin layer of the upper thermocline (Figure 2). They provided support for their hypothesis by an excellent agreement between the deglacial salinity variations at the source region of the ESPIW off southern Chile and the deglacial OMZ changes at millennial timescales. The mechanism operating behind this tight link is the sensitivity of the ESPIW subduction

process to fresh water input from the continent. According to modeling studies and field evidence, during the deglaciation, the melting of the Patagonian ice sheet discharged a fresh water volume of $222 \times 10^{12} \text{ m}^3$. We can picture this volume as equivalent to a fresh water cap with an area of $1.11 \times 10^6 \text{ km}^2$ and 200 m depth. This area would be larger than the modern outcropping region of the ESPIW [Karstensen, 2004; Schneider *et al.*, 2003], and sufficiently deep as to isolate the outcropping density surfaces from the contact of the atmosphere. Furthermore, the deglacial melting occurred in a time window of just about 300 years [Hulton *et al.*, 2002]. Following the same line of reasoning, we suggest that other previous mass fluctuations of the Patagonian ice sheet, although smaller, could have produced significant fresh water pulses that would alter the subduction rates of the ESPIW and thus the ventilation of the OMZ.

[35] In order to assess if there were hydrographic changes at the source area of the ESPIW that could have been associated with the millennial-scale variations of the OMZ off northern Chile during the last glacial, we have compared our $\delta^{15}\text{N}$ record with the sedimentary Fe content of the ODP Site 1233 off southern Chile [Kaiser *et al.*, 2005; Lamy *et al.*, 2004]. Unfortunately, direct estimations of paleosalinity off southern Chile are not yet available for the last 70 ka. Nevertheless, the sedimentary Fe content of ODP Site 1233 has been interpreted as being the result of glacial erosion processes that strongly enhanced the glaciofluvial sediment flux from Fe-rich basaltic volcanics in the Andes. It is intimately related to the dynamics of the Patagonian ice sheet, since its advances provided more Fe-rich material to be transported by rivers toward the continental margin [Kaiser *et al.*, 2005; Lamy *et al.*, 2004]. It can be seen in Figure 7 that there is millennial-scale coherence between our $\delta^{15}\text{N}$ record and the sedimentary Fe content at 41°S. Although the apparent covariance of these records does not constitute a proof of causation, we suggest that it is the manifestation of the changes in the subduction rates of the ESPIW triggered by fresh water pulses derived from the Patagonian Ice Sheet advance and retreat during millennial-scale temperature changes in the SH [Lamy *et al.*, 2004].

[36] This mechanism also serves to explain the relatively elevated $\delta^{15}\text{N}$ values in our core; despite that the OMZ volume was well ventilated by the ESPIW and NR was likely absent, as indicated by low glacial $\delta^{15}\text{N}$ values off Peru [Ganeshram *et al.*, 2000]. A northward displacement of the oceanographic systems and fronts that characterized the glacial would bring the subduction region of the ESPIW nearer to 30°S and also nearer to the OMZ. Thus greater ventilation is also indicative that the transport distance of nutrients from the subantarctic region along the Chilean coast was significantly shorter than today. In this scenario, it is likely that surface nutrients were not as depleted as today and hence newly subducted ESPIW would had a measurable preformed nitrate content that will eventually feed the upwelling farther north. By the time this subsurface water reached the Peru upwelling region however, nitrate concentrations would have been extremely low, analogous to the ESPIW off northern Chile today (De Pol-Holz *et al.*, submitted manuscript, 2006). In this scenario, nitrate

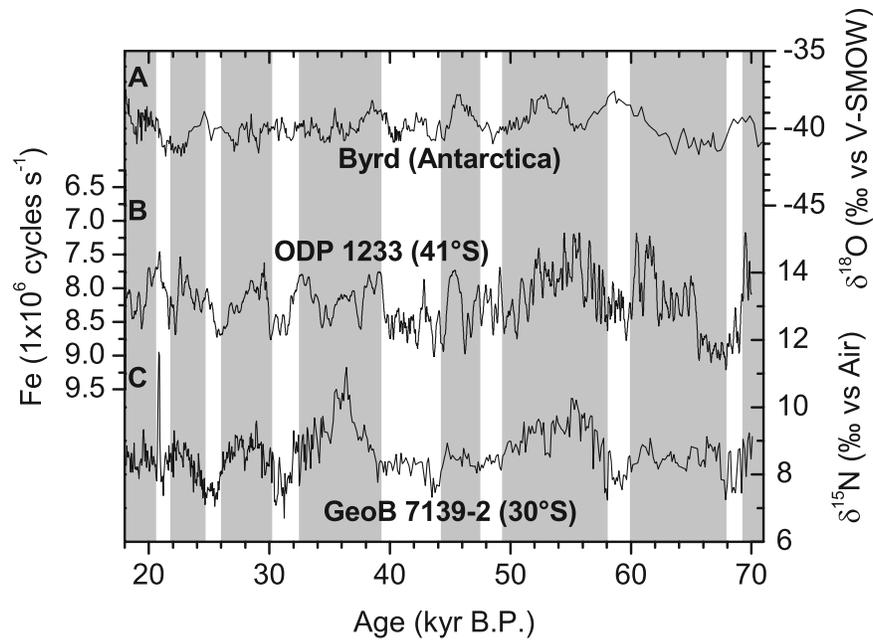

Figure 7. Comparison of geochemical data from northern and southern Chile sediment cores GeoB 7139-2 (30°S) and ODP Site 1233 (41°S) and Antarctic climate (Byrd ice core) during the last glacial epoch. (a) The $\delta^{18}\text{O}$ of ice in the Byrd ice core; (b) XRF-derived Fe content of ODP Site 1233 (inverse scale); and (c) $\delta^{15}\text{N}$ record of GeoB 7139-2. Shading represents periods with higher $\delta^{15}\text{N}$.

upwelled off central and northern Chile during the glacial was preformed and enriched in $\delta^{15}\text{N}$ because of phytoplanktonic assimilation during the alongshore transport. Off Peru, however, nitrate was most likely the product of mineralization and mixing with underlying waters (SAMW), which in absence of NR would have carried a relatively low $\delta^{15}\text{N}$ signal. However, if subduction stops, for example as a consequence of a melting pulse off southern Chile, the OMZ would have developed rapidly in the thermocline, promoting water column NR and elevating the $\delta^{15}\text{N}$ values. This mechanism relies on the presence of two oceanographic components: (1) the subtropical gyre circulation transporting subantarctic waters along the Chilean margin and (2) the presence of the PCU carrying subsurface waters from lower latitudes. We find very unlikely that one of these processes could have stopped completely during the relatively short timescale of our study.

6.2. NR Variability in the ESP in the Context of the Global NR Changes and Its Implications for the Late Quaternary Nitrogen and Carbon Cycles

[37] Late Quaternary NR variations in the NH-OMZs are highly correlated with the rapid climate transitions, known as the Dansgaard/Oeschger events, typical of the North Atlantic region during MIS 2 and 3. These rapid climate swings set a common pacing for the NH-NR rates, where warm interstadials were characterized by high NR rates and vice versa [Altabet *et al.*, 2002; Emmer and Thunell, 2000; Suthhof *et al.*, 2001]. In theory, the imbalances between the main source and sink terms in the marine nitrogen cycle, namely the nitrogen fixation [Capone *et al.*, 1997] and NR

(denitrification) [Codispoti and Christensen, 1985], can be considered as probable driving agents behind the CO_2 variation in the atmosphere at different timescales [Altabet *et al.*, 1995; Altabet *et al.*, 2002; Falkowski, 1997; Ganeshram *et al.*, 1995; McElroy, 1983]. The strength of the biological pump is directly influenced by the availability of nutrients such as NO_3^- . This fact links the ratio of nitrogen fixation to NR with the ability of the ocean to sequester CO_2 from the atmosphere. However, the net effect that an individual OMZ and changes in its NR intensity would have on the oceanic NO_3^- budget is a complex calculation that depends on, for example, the sum of the relative intensities of the NR process occurring in all OMZs of the ocean and the response exerted by the nitrogen fixation feedback due to changes in the oceanic N:P ratio [Tyrrell, 1999]. We have attempted nevertheless to qualitatively constrain the NR forcing on oceanic NO_3^- by smoothing the original NR curves with a running mean whose time window corresponds approximately to the residence time of the oceanic NO_3^- (3000 years [Altabet *et al.*, 2002]). This procedure results in the hypothetical NR forcing on the biological sequestration of CO_2 , which can then be compared with the atmospheric history recorded in ice cores. This idea was first introduced by Altabet *et al.* [2002] for the AS. We now include for the first time the contribution of the ESP for a global picture of the potential effect of NR on atmospheric CO_2 .

[38] In Figure 8 we have marked certain features of these records that resemble the observed variability in the late Quaternary evolution of atmospheric CO_2 . For example, between 40–60 ka B. P., the CO_2 rises about 20 ppmv

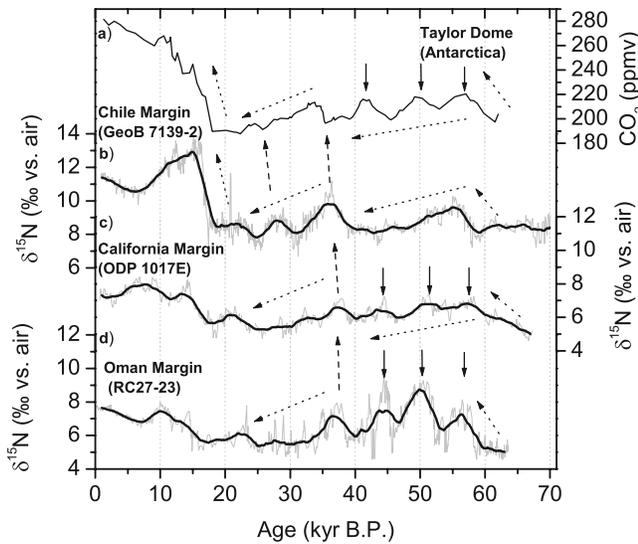

Figure 8. The late Quaternary history of the OMZ intensity in the three areas where modern-day nitrogen removal takes place, compared to the CO_2 concentration in the atmosphere. (a) CO_2 concentration in the Antarctic Taylor Dome ice core (composite data from *Indermühle et al.* [2000], *Indermühle et al.* [1999], and *Smith et al.* [1999]). (b) The $\delta^{15}\text{N}$ record of the eastern South Pacific (this study). (c) The $\delta^{15}\text{N}$ record of the eastern North Pacific [*Ganeshram et al.*, 2000; *Hendy et al.*, 2004; *Kienast et al.*, 2002]. (d) The $\delta^{15}\text{N}$ record of the Arabian Sea [*Altabet et al.*, 2002]. The light gray lines are the original data set, whereas the solid black line is a 3000 year running mean. See text for details.

(depicted with a dashed arrow). This rise was preceded by a persistent increase in the NR intensity in the ENP during 65–55 ka B. P., and by notorious increases in the AS and the ESP at 60 ka B. P. (dashed arrows). This 40–60 ka time window is later characterized by three CO_2 incursions with decreasing intensities at ~ 57 , 50 and 43 ka B. P. (marked with solid vertical arrows) that have been previously related to the NR forcing occurring in the AS [*Altabet et al.*, 2002] and also present in the ENP record, however not in the SH. The decreasing intensity of the CO_2 incursions between 60–40 ka B. P. might be related to a pronounced decreasing NR trend in the ESP and a moderate decreasing trend in the ENP (dashed arrows). Later, between 20–40 ka B. P., there are two CO_2 incursions starting at 35 and 26 ka B. P. Again, these incursions and their longer-term trend could be related to contemporaneous changes in the NR intensity of the three OMZs. Figure 8 shows that the CO_2 increase at 35 ka B. P. was preceded by NR maxima in the three OMZs at 36–37 ka B. P. (dashed vertical arrows) and that the smaller CO_2 increase at 26 ka B. P. was preceded by a NR maximum in the ESP at 27 ka B. P. The 15 ka decreasing trend in CO_2 is also present in the three OMZs (dotted arrows).

[39] All of these features can be summarized by constructing an index of the global NR forcing on atmospheric CO_2 . The index is simply the sum of the smoothed normalized $\delta^{15}\text{N}$ data from the three OMZs (Figure 9). The two basic assumptions here are (1) that the isotopic change recorded in sediments is approximately linearly related to the amount of nitrate that is being denitrified above in the water column and (2) that the slope of this linear relation is similar in the three OMZs. The first assumption holds if the reactant (NO_3^-) is continuously supplied to and partially consumed at the thermocline, as

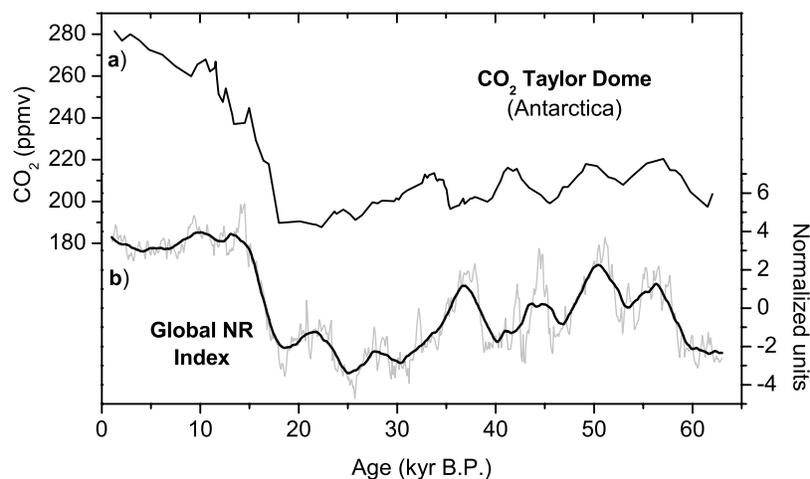

Figure 9. Comparison of the atmospheric CO_2 concentration from the Taylor-Dome ice core (a) with the global nitrogen removal (NR)-forcing index (b). The global NR-forcing index was calculated by adding the individual normalized OMZ-NR contribution. The N isotopic normalization was done by subtracting from each $\delta^{15}\text{N}$ record its mean and dividing them by its standard deviation. The oceanic NO_3^- response to the NR forcing can be estimated as the negative of the 3000 year moving average (solid black line).

is the case for an open ocean site with continuous diffusion/advection of NO_3^- , like in all OMZs [Sigman and Casciotti, 2001]. The second one is probably valid because the isotope effects of NR in the different OMZs are similar [Brandes et al., 1998; Liu et al., 1987; Voss et al., 2001].

[40] Our normalized NR-forcing index (Figure 9) shows a remarkable resemblance to the late Quaternary history of atmospheric CO_2 . With the inclusion of the SH contribution, our index matches the millennial-scale evolution of the atmospheric CO_2 during the late Quaternary in greater detail than through the comparison of the AS history alone [Altabet et al., 2002]. For example, between 40–60 ka B. P., apart from the presence of the three millennial-scale incursions, the clear decreasing trend that is present in the CO_2 record is now fully featured in the NR forcing. Moreover, the deglacial CO_2 rise is matched both in timing and intensity by the NR forcing once the SH is considered.

[41] The general consistency of both curves indicates a close coupling between the oceanic N cycle and atmospheric CO_2 , despite recent evidence that suggests glacial-interglacial difference in NR has a minor impact upon the global NO_3^- budget and primary production [Deutsch et al., 2004; Gruber, 2004]. We propose that in addition to the modulation of global oceanic NO_3^- there is an alternative link between the NR and atmospheric CO_2 , the physical pump. Low NR rates during the cold stadial periods of the Quaternary imply a better-ventilated thermocline in the ocean regions where the modern OMZs lie. The opposite occurs during various warm interstadials, where poor thermocline ventilation is observed. The augmented or diminished physical ventilation rates of the intermediate water masses, particularly the less-considered midlatitude intermediate water masses like the ESPIW, could play an important role in modulating the millennial-scale CO_2 sequestration by the ocean. Colder water, a deeper penetration and enhanced formation rates and volumes would favor more CO_2 sequestration by the ocean during low NR-stadial periods and vice versa. Our hypothesis is suitable to be tested in the near future by means of new paleoceanographic studies. However, we would like to point, that regardless of whether the link between NR and atmospheric CO_2 be governed by biological or physical processes, the agreement between the normalized isotopic data and the CO_2 concentrations during the last ~65 ka B. P. is strong evidence of a

tight connection between the N and C cycles during the late Quaternary at multiple timescales.

7. Summary and Conclusions

[42] High-resolution nitrogen isotope data from the Chilean continental margin during the last ice age show that the intensity of the OMZ in the ESP varied significantly at millennial timescales, with an intrinsic SH rhythm, and with no signs of an ENSO-like or Dansgaard/Oeschger type of forcing coming from the Equatorial Pacific. The reorganizations of the OMZ ecosystem were most probably caused by an extratropical process: variation in the thermocline ventilation in the midlatitude formation area of the ESPIW. Moreover, a link between NR and local primary production is not supported by our data. Millennial-scale changes in the size of the Patagonian ice sheet brought time dependant alterations in the fresh water supply from the continent to the adjacent ocean, which were faithfully recorded by the sedimentary Fe content records and salinity changes off southern Chile. Such fresh water pulses probably added enough buoyancy in the outcropping region of the density surfaces that bound the OMZ vertical distribution today, that it impeded the subduction of subantarctic waters and the ventilation of the subsurface ESP, promoting the existence of an OMZ and leaving a measurable sedimentary record of NR. On this basis, we can conclude that the OMZ in the ESP experienced an intrinsic SH timing with no evident connection with NH rapid climate changes. When the SH contribution to the NR forcing on atmospheric CO_2 is included, it results in a global forcing that matches almost every millennial-scale feature of the CO_2 evolution during the last 70 ka. On this basis, oceanic NR occurring in the world's OMZs is a key component of the marine feedback to climate forcing not only at orbital [Liu et al., 2005], but also at multiple timescales.

[43] **Acknowledgments.** We gratefully acknowledge Mea Cook, Laura Fariás, Carina Lange, and Práxedes Muñoz for comments and help. This work was funded by the Chilean National Commission for Scientific and Technological Research (CONICYT) through the FONDAP Program and by the Fundación Andes. Additional support was provided by the German Ministry for Science and Education through the PUCK project. R.D.P.H. was supported by graduate fellowships coming from Fundación Andes, CONICYT, and MECESUP/UCO2002. This work improved considerably thanks to the comments of two anonymous reviewers.
