ABSTRACT

We analyze bathymetric and gravity anomalies at five plume-ridge systems to constrain crustal and mantle density structure at these prominent oceanic features. Numerical models are then used to explore the physical mechanisms controlling plume-ridge interaction and to place theoretical constraints on the temperature anomalies, dimensions, and fluxes of the Icelandic and Galápagos plumes.

In Chapter 1 we analyze bathymetric and gravity anomalies along the hotspot-influenced Galápagos Spreading Center. We find that the Galápagos plume generates along-axis bathymetric and mantle-Bouguer gravity anomalies (MBA) that extend >500 km east and west of the Galápagos Islands. The along-axis MBA becomes increasingly negative towards the plume center, reaching a minimum of ~90 mGal near 91°W, and axial topography shallows by ~1.1 km toward the plume. These variations in MBA and bathymetry are attributed to the combined effects of crustal thickening and anomalously low mantle densities, both of which are due to a mantle temperature anomaly imposed beneath the ridge by the Galápagos plume. Passive mantle flow models predict a temperature anomaly of 50±25 °C is sufficient to produce the 2-4 km excess crust required to explain the along-axis anomalies. 70-75% of the along-axis bathymetric and MBA variations are estimated to arise from the crust with the remaining 25-30% generated by the anomalously hot, thus low-density mantle. Along Cocos-plate isochrons, bathymetric and MBA variations increase with increasing isochron age, suggesting the subaxial mantle temperature anomaly was greater in the past when the plume was closer to the ridge axis.

In addition to the Galápagos plume-ridge system, in Chapter 2 we examine along-isochron bathymetric and MBA variations at four other plume-ridge systems associated with the Iceland, Azores, Easter and Tristan hotspots. We show that residual bathymetry (up to 4.7 km) and mantle-Bouguer gravity anomalies (up to ~340 mGal) are greatest at on-axis plumes and decreases with increasing ridge-hotspot separation distance, until becoming insignificant at a plume-ridge separation of ~500 km. Along-isochron widths of bathymetric anomalies (up to 2700 km) decrease with increasing paleo-spreading rate, reflecting the extent to which plume material flows along-axis before being swept away by the spreading lithosphere. Scaling arguments suggest an average rideward plume flux of ~2.2x10^6 km/my. Assuming that the amplitudes of the MBA and bathymetric anomalies reflect crustal thickness and mantle density variations, passive mantle flow models predict...
maximum subaxial mantle temperature anomalies to be 150-225°C for ridge-center plumes, which decrease as the ridges migrate away from the plumes.

The dynamics of mantle flow and melting at ridge-centered plumes are investigated in Chapters 3 using three-dimensional, variable-viscosity, numerical models. Three buoyancy sources are examined: temperature, melt depletion, and melt retention. The width $W$ to which a plume spreads along a ridge axis depends on plume volume flux $Q$, full spreading rate $U$, buoyancy number $B = \frac{(Q\Delta \rho g)}{(48\eta_0 U^2)}$, and ambient/plume viscosity contrast $\gamma$ according to $W = 2.37\left(\frac{Q}{U}\right)^{1/2}(B\gamma)^{0.04}$. Thermal buoyancy is first order in controlling along-axis plume spreading while latent heat loss due to melting, and depletion and retention buoyancy forces contribute second order effects. Two end-member models of the Iceland-Mid-Atlantic Ridge (MAR) system are examined. The first end-member model has a broad plume source of radius 300 km, temperature anomaly of 75°C, and volume flux of $1.2 \times 10^7$ km$^3$/my. The second model has a narrower plume source of radius 60 km, temperature anomaly of 170°C, and flux of $2.1 \times 10^6$ km$^3$/my. The first model predicts successfully the observed crustal thickness, topographic, and MBA variations along the MAR, but the second model requires substantial along-axis melt transport in order to explain the observed along-axis variations in crustal thickness, bathymetry, and gravity. We favor this second model because it predicts a mantle P-wave velocity reduction in the plume of ~2% as consistent with recent seismic observations beneath Iceland.

Finally in Chapter 4 we use three-dimensional numerical models to investigate the interaction of plumes and migrating midocean ridges. Scaling laws of axial plume spreading width $W$ are derived first for stationary ridges and off-axis plumes, which yield results consistent with those obtained from independent studies of Ribe [1996]. $W$ and the maximum plume-ridge interaction distance $x_{max}$ again scale with $(Q/U)^{1/2}$ as in the case of ridge-centered plumes and increase with $\gamma$ and buoyancy number. In the case of a migrating ridge, $x_{max}$ is reduced when a ridge migrates toward the plume due to excess drag of the faster-moving leading plate, and enhanced when a ridge migrates away from the plume due to reduced drag of the slower-moving trailing plate. Thermal erosion of the lithospheric boundary layer by the previously ridge-centered plume further enhances $W$ and $x_{max}$ but to a degree that is secondary to the differential migration rates of the two plates. Model predictions are compared with observed along-isochron bathymetric and MBA variations at the Galápagos plume-ridge system. The anomaly amplitudes and widths, as well as the increase in anomaly amplitude with age are predicted with a plume source temperature anomaly of 80-120°C, radius of 80-100 km, and volume flux of $4.5 \times 10^6$ km$^3$/my. Our numerical models also predict crustal production rates of the Galápagos Islands consistent with those estimated independently using the observed island topography. Predictions of the geochemical signature of the plume along the present-day ridge suggest that mixing between the plume and ambient mantle sources is unlikely to occur in the asthenosphere or shallow crust, but most likely deeper in the mantle possibly by entrainment of ambient mantle as the plume ascends through the depleted portion of the mantle from its deep source reservoir.

ACKNOWLEDGMENTS

I most likely would not have found my way to marine geophysics had it not been for my undergraduate professor at Colorado College, Dick Hilt, who managed to coax me into going on a research cruise in the western Pacific with Marcia McNutt. It is largely due to Marcia that I made it to the MIT/WHOI Joint Program, and ever since my sea-going introduction to marine geophysics she has provided much selfless and enthusiastic support as a teacher, advisor, and collaborator. My thesis advisor Jian Lin is someone to whom I will be eternally grateful. Jian's patient, thorough, and dedicated advising has provided me with invaluable guidance through a whole spectrum of processes one must learn as a graduate student and young scientist: everything from critical analysis of data, to the planning and design of a research project—not to mention entering the correct account number on ones Federal Express package. I could not had hoped for a better thesis advisor. Furthermore, I thank Bob Detrick for contributing valuable input to each of my thesis chapters and for providing advice in other research activities.

I am also extremely fortunate to have worked with Carl Gable at Los Alamos whose numerical code and tutoring in numerical methods was fundamental to the later part of my thesis work. I have fond memories of the warm New Mexico evenings spent with Carl and Peter van Keken discussing the rigors (and not-so-rigors) of mantle convection calculations over roasted green chiles and margaritas. Furthermore, I give special thanks to Chris Kincaid who allowed me the opportunity to work with him on laboratory tank experiments of plume-ridge interaction which were great fun and provided a unique approach to studying plume-ridge systems. I gratefully acknowledge Jean-Guy Schilling for contributing valuable insight and suggestions to much of my work here at Woods Hole.

My education in geology, igneous petrology, and geochemistry (not to mention my heighten appreciation for fine dining) comes largely from Henry Dick's Geodynamics Seminar which brought to Woods Hole whole hosts of prominent speakers and provided numerous field trips to sites that I would otherwise never have experienced. I also thank the individuals who have made these and other department seminars such wonderfully interactive learning experiences and with whom I have shared numerous stimulating discussions. Among them are Peter Clift, Stan Hart, Deborah Hassler, Stefan Hussenoeder, Greg Hirth, Graham Kent, Peter Kelemen, Ken Koga, Laura Magde, Alberto Saal, Hans Schouten, Yang Shen, Deborah Smith, and Jack Whitehead.

I owe much thanks to the many MIT and WHOI graduate students for their personal and professional support and for helping make graduate school as enjoyable as it has been. As senior graduate students Carolyn Ruppel, Mathew Cordery, Paul Filmer, Gail Christesen, and Cecily Wolfe were excellent role models during my beginning graduate school years. My first classes at MIT would have been much tougher without Helen Webb's eagerness in working with me through various class assignments. I thank Emilie Hooft for her helpful discussions of Chapter 2 and encouragement through the other chapters. Without doubt, my experience in the WHOI Joint Program would have been very different without Javier Escartín, whose animated personality kept me laughing and who's scientific ideas kept me thinking; and without Gary Jaroslow, whose positive nature kept me level headed during challenging times and whose impromptu discussions were as stimulating as they were helpful.

Finally, I enthusiastically thank the WHOI Education Office whose efforts are commended for contributing to a top notch graduate education and research program.
With love to my parents,
Janice and Floyd Ito
for giving so much

**Chapter 3**
INTRODUCTION

Hotspots and midocean ridges are the sources of the ocean's igneous crust and are thus the primary mechanisms by which heat and mass are transported from the mantle to the Earth's surface. The present-day global oceanic crustal production rate of $2 \times 10^7$ km$^3$/my, of which $\sim$10% is due to hotspot volcanism [Larson, 1991] is sufficient to resurface the planet with a 7 km-thick crust every 175 m.y. years. Moreover, crustal production rates may have been greater by a factor of 2 in the geologically recent past [Larson, 1991]. Thus, studies of igneous and mantle dynamic processes at hotspots and midocean ridges are crucial to our understanding of Earth structure at present-day and in the past.

Over the past three decades much has been learned about the dynamics of mantle flow and melt generation at hotspots and midocean ridges. Since Hess's [1962] hypothesis that midocean ridges are the ascending limbs of mantle convection cells, a number of observational and theoretical studies have shaped our present conceptions of midocean ridge dynamics. For example, Hess's [1962] convection hypothesis was examined quantitatively by means of a boundary layer treatment of cell convection in two-dimensions (2-D) [Oxburgh and Turcotte, 1967; Turcotte and Oxburgh, 1967]. The study by Oxburgh and Turcotte [1967] was among the first to establish the concept of a lithospheric thermal boundary layer, to explain the decrease in seafloor heat flow with age, and to discuss decompression melting processes at midocean ridges. A parallel study by McKenzie [1967] was among the first to explain seafloor heat flow variations by a conductively cooling plate model overlying an asthenosphere of uniform temperature.

Furthermore, the finding that normal oceanic crust was $\sim$6 km in thickness, globally [Raitt, 1963], provides a powerful constraint on mantle flow and thermal structure beneath midocean ridges. Reid and Jackson [1981] demonstrated that simple 2-D corner flow models could produce the mantle temperatures and upwelling rates necessary to generate a 6-km thick crust at intermediate and fast spreading rates. Thermal and compositional buoyancy, however, seemed to be required to generate 6 km of crust at slow spreading rates [e.g. Buck and Su, 1989; Rabinowicz, 1987; Scott and Stevenson, 1989; Sotin and Parmentier, 1989]. Further work such as that of Bottinga and Allègre [1978], Klein and Langmuir [1987], McKenzie [1984], and McKenzie and Bickle, [1988] were groundwork studies of the thermal dynamics of mantle melting at ridges and on the composition of ocean ridge basalts.
During the time that seafloor spreading was being recognized as the surface expression of a convecting Earth, hotspots were also being attributed to mantle processes, separate from, but consistent with, the plate tectonic paradigm. Wilson [1963] introduced the concept that the age progression along the Hawaiian Island chain reflects migration of the lithospheric plate over a magma source which is fixed in the mantle. Such findings led to Morgan's hypothesis that hotspots are the result of mantle convection plumes which ascend from the deep mantle to the base of the lithosphere [Morgan, 1971; Morgan, 1972]. Follow-up theoretical studies by Parmentier et al. [1975] and laboratory experiments of Whitehead and Luther [1975] demonstrated that Rayleigh-Taylor instabilities from a basally heated mantle could generate localized upwelling in the form of plumes. Along with the plume hypothesis came studies by Crough [1978, 1983], who attributed the broad (1000-2000 km) hotspot swells to anomalously hot, low-density lithosphere, and work by Detrick and Crough [1978], which introduced the concept of plume-induced lithospheric thinning. Later work by Olson and colleagues showed that hotspot swells could be explained by the dynamic uplift of a plume as it spreads gravitationally beneath the lithosphere [Olson 1990; Olson and Nam, 1986; Olson et al., 1988]. Finally, Watson and McKenzie [1991] combined the physics of a buoyantly upwelling plume with melting models of McKenzie and Bickle [1988] to examine melting processes beneath the Hawaiian hotspot.

A landmark discovery by Schilling and co-workers demonstrated that igneous products at hotspots such as Hawaii, Iceland, Galápagos, and the Azores have rare-earth element compositions distinct from typical midocean ridge basalts (MORB) [Schilling, 1971, 1973, 1975, Schilling et al., 1976; Schilling and Winchester, 1967]. Moreover, their findings of hotspot-type chemical signatures in basalts at hotspot-like swells along midocean ridges, such as Iceland on the Mid-Atlantic Ridge, led to the concept that rising mantle plumes interact with and feed oceanic spreading centers [Hart et al., 1973; Schilling, 1971, 1973, 1975; Schilling and Winchester, 1967; Sun et al., 1975]. Independent studies of plate kinematics led to Morgan [1978]'s idea of a "second type of hotspot island" which also suggested that plumes spread horizontally to nearby oceanic spreading centers; while Vogt [1971, 1972, 1976] showed evidence that plumes inject material also along the axes of midocean ridges. These original studies stimulated numerous geophysical and geochemical surveys of plume-ridge systems leading to papers by Schilling and co-workers which have shaped concepts today of how mantle plumes may interact with midocean ridges [e.g. Schilling, 1985, 1991; Schilling et al., 1985].
With the conceptual frameworks of midocean ridges, plumes, and the interaction of plumes and ridges established, the purpose of this thesis is to examine quantitatively the mantle and crustal structure of plume-ridge systems and the causal mantle dynamic and igneous processes. The first two chapters focus on using bathymetric and gravity observations to infer crustal and mantle density structure at the Galápagos (Chapter 1), Iceland, Azores, Tristan, and Easter (Chapter 2) plume-ridge systems. The last two chapters focus on the dynamics of mantle flow and melting at plume-ridge systems, which are investigated with numerical models as constrained by the geophysical observations.

In Chapter 1, we investigate the crustal thickness and mantle temperature variations along the Galápagos Spreading Center imposed by the Galápagos plume. The mantle-Bouguer gravity anomaly (MBA)—which is the free-airy gravity anomaly corrected for the attraction of seafloor topography and the crust-mantle interface assuming a reference crust of uniform density and thickness—has been particularly useful in understanding subsurface density structure at midocean ridges. For example, bulls-eye shaped MBA lows centered on individual ridge segments as documented by Kuo and Forsyth [1988] and Lin et al. [1990] are strong evidence that crustal accretion at slow-spreading ridges varies significantly along-axis and that this accretion may occur due to convective upwelling as hypothesized by Whitehead et al. [1984]. In Chapter 1 we produce maps of MBA anomaly and bathymetry, both of which reflect variations in crustal thickness and mantle density at the Galápagos ridge due to the excess temperature imposed by the Galápagos hotspot.

Temperature anomalies and the structure of mantle plumes at intraplate hotspots are reflected directly in the shape and amplitude of hotspot swells [e.g. McNutt, 1987; Sleep 1987, 1990]. At near-ridge hotspots such as the Galápagos, however, the mantle temperature anomaly at the ridge-axis is likely to enhance crustal production; consequently, investigations of mantle temperature anomalies at near-ridge hotspots requires the consideration of melting. We therefore use 3-D passive flow models—analogous to the corner flow description of Reid and Jackson [1981]—of the Galápagos Spreading Center to predict thickness variations along the ridge axis due to a range of axial temperature anomalies. The combined contributions of crustal thickness and mantle density variations to bathymetry and MBA are then compared with observations to constrain mantle temperature. Similar analyses are done for anomalies along Cocos-Plate isochrons to infer crustal thickness variations and associated mantle temperature anomalies in the past when the Galápagos Spreading Center was closer to the Galápagos plume.
Analyses of bathymetric and MBA variations along isochrons is a unique method of investigating the evolution of individual plume-ridge systems. In Chapter 2 we investigate along-axis and along-isochron anomalies at five prominent systems associated with the Galápagos, Azores, Iceland, Tristan, and Easter hotspots. In addition we use independent constraints on past plate motions to estimate plume-ridge separation distances and spreading rates at times corresponding to the isochron ages. We investigate relationships between bathymetric and MBA amplitudes and paleo-plume-ridge distance, as well as between widths of along-isochron bathymetric anomalies and paleo-spreading rate. Scaling laws are then derived for the dependence of anomaly amplitudes and mantle temperature anomalies to examine how axial temperature anomalies of the five systems may have changed with plume-ridge distance.

While the passive flow models used in Chapters 1 and 2 are reasonable approximations of the flow beneath oceanic spreading centers, they are poor representations of the flow structure at buoyantly upwelling plumes. To investigate the dynamics of mantle flow and melting at plume-ridge systems it is therefore necessary to incorporate both the flow beneath a spreading center system as first investigated by Turcotte and Oxburgh, as well as the pertinent physics of plume convection as originally identified by Parmentier et al., [1975] and Whitehead and Luther, [1975]. Thus, in Chapter 3 we used numerical models to simulate the 3-D interaction between ridge-centered buoyant plumes and oceanic spreading centers. We consider fully pressure- and temperature-dependent rheology and investigate buoyancy due to thermal expansion, melt depletion, and melt retention. First, scaling laws are derived for the dependence of along-axis plume width on plume flux, ridge spreading rate, and ambient/plume viscosity contrast in the absence of melting. We then investigate the melting effects of latent heat loss, and depletion and retention buoyancy on flow structure and on the scaling laws. Finally, we apply our models to the Iceland-Mid-Atlantic Ridge system. Model predictions and observations of along-axis crustal thickness, bathymetry, MBA, and geochemical variations are compared for two plume source radii and temperature anomalies which represent end-member properties of the Icelandic plume source.

The purpose of the last chapter is to investigate the fluid dynamics of plume-migrating ridge interaction. An important aspect is to test quantitatively the "mantle plume source/migrating ridge sink" hypothesis originally proposed by Schilling and co-workers as based on their geochemical findings as well as the work of Morgan and Vogt. Scaling laws are first derived for off-axis plumes in steady state with stationary midocean ridges.
and are compared with independent but parallel studies of Ribe [1996]. For migrating ridge cases, we then investigate how along-axis plume width and maximum plume-ridge interaction distance scale with ridge migration rate, spreading rate, plume flux, and ambient/plume viscosity. The model is then tested by comparing model predictions with bathymetric and MBA observations of the Galápagos plume-migrating ridge system. Anomalies are compared at the present-day ridge axis as well as at the Cocos Plate isochrons examined in Chapter 1. We also compare predictions and observations of the geochemical signature of the Galápagos plume along the Galápagos Spreading Center in order to investigate the processes of mixing between the plume and ambient mantle sources.

Finally I include in the Appendix, laboratory tank experiments done with C. Kincaid and C. Gable on off-axis plume-ridge interaction. A plume and ridge upper mantle system is simulated with a tank of concentrated sucrose solution in order to investigate the primary mechanisms that allow an off-axis plume to overcome the viscous drag of a spreading plate to feed the nearby ridge.

MANTLE TEMPERATURE ANOMALIES ALONG THE PRESENT AND PALEOAXES OF THE GALAPAGOS SPREADING CENTER AS INFERRED FROM GRAVITY ANALYSES
Mantle temperature anomalies along the present and paleoaxises of the Galápagos spreading center as inferred from gravity analyses

Garrett T. Ito and Jian Lin
Department of Geology and Geophysics, Woods Hole Oceanographic Institution, Woods Hole, Massachusetts

Abstract. To better understand the effects of hot spots on mid-ocean ridge thermal structure, we investigate the subsurface density structure of the Galápagos spreading center and nearby lithosphere. Using shipboard gravity and bathymetry data, we obtain maps of mantle Bouguer anomalies (MBA) by removing from the free-air gravity the attractions of seafloor topography and a 6-km-thick model crust. Comparison of observed and theoretical MBA profiles along isochrons for ages 0.0-7.7 Ma suggests that seafloor topography is isostatically compensated by mass anomalies primarily in the upper 100 km of the mantle. This result is consistent with the notion that seafloor topography along the Galápagos spreading center is supported by lateral changes of crustal thickness and upper mantle density, both of which are controlled by temperatures in the upper mantle where decompression melting occurs. Along the ridge axis, the MBA decreases from the east and west toward the Galápagos hot spot by ~90 mGal, reaching a minimum nearest the hot spot at 91°W. Seafloor topography mirrors the MBA along axis, increasing by ~1.1 km toward the hot spot. These variations in MBA and bathymetry can be explained by crustal thickening and mantle density variations resulting from a gradual axial temperature increase of 50±25°C toward the hot spot. The predicted crustal thickening of 2-4 km nearest the hot spot accounts for 70-75% of the along-axis MBA and bathymetry anomalies; mantle density variations account for the rest of the anomalies. From the crustal isochron of age 7.7 Ma to the present-day axis, the along-isochron amplitudes of MBA decrease from ~150 to ~90 mGal. The corresponding along-isochron bathymetry anomalies decrease from ~1.7 to ~1.1 km. These observations along the paleoaxises of the Galápagos spreading center indicate that the axial temperature anomaly was ~70°C hotter in the past (86±25°C) and has steadily decreased to 50±25°C as the ridge axis migrated away from the Galápagos hot spot. These along-isochron temperature anomalies, however, have remained well below that estimated for the hot spot itself (200°C), indicating that the lateral temperature gradient between the hot spot and the ridge axis has remained 10-20 times greater than along the ridge axis over the past 7.7 m.y.

Introduction

Three-dimensional gravity studies of mid-ocean spreading centers have proven crucial to understanding the processes controlling oceanic lithosphere accretion. For example, it has been shown that gravity and seafloor depth vary systematically along individual spreading segments [e.g., Kuo and Forsyth, 1988; Prince and Forsyth, 1988; Lin et al., 1990; Detrick et al., 1995] and appear to be spreading-rate-dependent [Parmentier and Phipps Morgan, 1990; Lin and Phipps Morgan, 1992; Sparks et al., 1993]. Such variations in gravity and bathymetry indicate segment-scale changes in crustal thickness and/or mantle density and reflect anomalies in along-axis mantle temperatures. Near hot spots, however, the extent of along-axis variation in density structure is broader than individual ridge segments, indicating a larger scale influence by mantle plumes [Anderson et al., 1973; Cochran and Talwani, 1977; Bell and Buck, 1992]. The influence of mantle plumes on crustal composition is also evident by enrichments of trace elements and isotopes along the Reykjanes Ridge near the Iceland hot spot [Hart et al., 1973; Schilling, 1973, 1975a; Vink, 1984], along the Mid-Atlantic Ridge near the Azores hot spot [White et al., 1975, 1976; Schilling, 1975b], and along the Galápagos spreading center near the Galápagos hot spot [Schilling et al., 1976, 1982; Verma and Schilling, 1982; Verma et al., 1983].

The Galápagos spreading center is an excellent example of an oceanic ridge influenced by a nearby hot spot. At present-day, the spreading center lies ~170 km north of the Galápagos hot spot and separates the Cocos Plate to the north and the Nazca Plate to the south with a full spreading rate of 4.5-6.8 cm/yr [DeMeis et al., 1990] (Plate 1a). Spreading segments of the Galápagos spreading center trend east-west and are joined by north-south trending transform faults. Hey [1977] proposed that the Galápagos hot spot began forming the Cocos and Carnegie Ridges ~20 Ma and then migrated southwest with respect to the Cocos Plate as it continued accreting the Cocos Ridge. The spreading center crossed over the hot spot ~10 Ma as the Galápagos Archipelago began its formation on the Nazca Plate.

As for the present-day interaction between the hot spot plume and spreading center, it was first suggested by Morgan [1978]
Plate 1. (a) Tectonic map of the Galápagos spreading system encompassing the study region (rectangular box). The solid dark lines mark the ridge axis, and the arrows show the estimated absolute plate motion relative to the hot spot reference frame. (b) Color-shaded map of shipboard and DBDB5 bathymetry illuminated from the north and contoured at 500-m intervals. Depths shallower than 1.6 km are colored red, while those deeper than 3.6 km are colored violet. Grid spacing is 5-min. The spreading center is marked by solid white lines and the gravity ship tracks are marked by white dotted lines. (c) Color map of free-air gravity along ship tracks with contour interval of 10 mGal and gridded with 5-min spacing. Gravity values >20 mGal are colored red, while those <30 mGal are colored violet. The contours are drawn from interpolated values between ship tracks and are masked in regions with no data.
that Galápagos plume material feeds through a mantle conduit into the Galápagos spreading center giving rise to the Wolf-Darwin seamount chain (Plate 1b). Plume-fed mantle flow along axis was suggested by Vogt [1976] to explain the uniform increase in along-axis topography toward the hot spot. Further evidence for plume flow toward and along the spreading center is rare earth enrichments along the ridge, first documented by Schilling et al. [1976]. Subsequent studies of along-axis variation in rare earth element and isotopic ratios support ideas of plume entrainment to the ridge axis and along-axis dispersion of plume material [Verma and Schilling, 1982; Verma et al., 1983; Schilling, 1985].

In this paper we present evidence for a regional mantle temperature anomaly and an associated crustal thickness variation beneath the Galápagos spreading center imposed by the Galápagos hot spot. We first isolate the subsurface component of the gravity field by making topographic and crust-mantle interface corrections (the mantle Bouguer corrections). We next examine topographic compensation mechanisms both on- and off-axis by comparing theoretical and observed mantle Bouguer gravity anomalies along isochrons for models of compensation from crustal thickness variations (Airy compensation) and compensation from laterally varying mantle densities (Pratt compensation). Given the constraints on the depth of compensation, we then examine models of crustal and mantle density structure to constrain mantle temperatures along the present-day Galápagos spreading center. Finally, we discuss the temporal evolution of axial mantle temperatures in the past 7.7 m.y. and its implications for the evolution of this hot spot-ridge system.

Data

Our approach for investigating mantle temperature anomalies requires accurate constraints on subsurface density structure which is reflected directly by gravity and seafloor topography. The gravity and bathymetry data we use are shipboard data obtained from the National Geophysical Data Center and the Lamont-Doherty Earth Observatory. The data set covers a region within 84.4°-98.1°W and 3.0°S-4.3°N, encompassing the Galápagos spreading center and the Galápagos hot spot (Plate 1b). We also use high-resolution gravity and bathymetry data from a dense survey around the 95.5°W propagating rift tip [Phipps Morgan and Kleinrock, 1991]. The bathymetry data are shipboard depth soundings supplemented with digital bathymetry (DBDBS) between ship tracks. DBDBS data points within 5 min of a ship data point are eliminated and the combined data set is regridded with 5-min grid spacing to produce the bathymetry map shown in Plate 1b. A regional bathymetric swell encompassing the Galápagos Archipelago spans ~1300 km along the ridge axis. The swell shallows along the ridge axis toward 91°W by 1.1 km and peaks near the Galápagos hot spot which is centered beneath the island Fernandina [White et al., 1993] (see Figure 1b for along-axis profile).

In order to improve the internal consistency of the gravity data we use the method of Prince and Forsyth [1984] to minimize discrepancies in gravity measurements at ship track crossings. Applying the appropriate DC shifts to straight-line track segments reduces the total rms crossover error from 11.2 to 5.5 mGal. The value of 5.5 mGal is therefore our estimate for data uncertainty. After applying these corrections we produce the 5-min grid of free-air gravity shown in Plate 1c. In this map we observe short-wavelength (<100 km) peaks coinciding with topographic highs; the lowest free-air gravity (~90 mGal) occurs over the flexural most of the Galápagos Archipelago and the highest (+60 mGal) occurs over the southeastern flank of the island of Isabela (see Plate 1b for location of Isabela). The total variation in free-air gravity along the ridge axis is ~40 mGal.

We use only shipboard gravity rather than satellite-altimetry-derived gravity because the released satellite data coverage in this region is still sparse and the shipboard gravity is more accurate. The other reason for using only shipboard gravity concerns the accuracy of topographic corrections which rely on accurate bathymetric measurements. Since shipboard gravity and bathymetric measurements are taken at the same points, topographic corrections to the free-air gravity are the most accurate possible.

Gravity Data Reduction

A significant portion of the free-air gravity is caused by seafloor topography. Therefore, to investigate subsurface density structure, to which we will relate mantle temperature anomalies, we apply a mantle Bouguer correction. Using Parker's [1973] spectral method, we subtract from the free-air gravity the theoretical gravity signal of the seafloor-water interface and crust-mantle (Moho) interface assuming a crustal layer of constant thickness (6 km) and density (2800 kg/m^3). We take the density of the mantle to be 3300 kg/m^3.

The resulting mantle Bouguer anomaly (MBA) shows that most of the short-wavelength (<100 km) variations caused by local topography are removed, leaving a broad oval-shaped negative anomaly aligned along the spreading axis between ~97°W and ~85°W (outlined by yellow shading, Plate 2a). Superimposed on this oval-shaped anomaly are high-amplitude negative branches over the Cocos Ridge (~100 mGal) and Galápagos Archipelago (~300 mGal) reflecting the thickened crust of these edifices. Along the ridge axis, 10-20 mGal variations in MBA occur at segmentation length scales (100-200 km), but the most prominent feature is the long-wavelength decrease by ~90 mGal along axis toward 91°W (Plate 2b). For comparison with other oceanic spreading centers, this 90-mGal anomaly is approximately twice the segmentation-scale MBA variation along the Mid-Atlantic Ridge [e.g., Lin et al., 1990; Detrick et al., 1995] and about 10 times the MBA variation along the East Pacific Rise (8.8°-13.5°N) [Madison et al., 1990].

The minimum in MBA occurs near 91°W on the southern segment of the 91°W-transform offset, which is also the point of the ridge axis closest to the Galápagos hot spot (point P, Plate 2a). The decrease in MBA is nearly symmetric about point P and uniform along the 650-km ridge length to each side of point P. This wavelength is comparable in extent to topographic swells of other hot spots such as Hawaii (~1500 km across the island chain), Cape Verde (~1500 km in diameter) [Crough, 1983], and Iceland (~2000 km in diameter) [White, 1988].

Comparison of this along-axis MBA with along-axis variations in bathymetry and basalt chemistry reveals a close correlation between the four anomalies (Figure 1). All anomalies peak at or near point P, all extend over comparable length scales, and all decrease in amplitude nearly symmetrically eastward and westward away from point P. The peak in the La/Sm anomaly coincides with that of K2O, MgO, and a minimum in FeO [Schilling et al., 1982], while the peak in $^{87}$Sr/$^{86}$Sr coincides with a minimum in $^{143}$Nd/$^{144}$Nd [Verma et al., 1983]. Both geochemical signatures are attributed to a source heterogeneity associated with the Galápagos hot spot [Verma et al., 1983]. Although the peak in $^{87}$Sr/$^{86}$Sr occurs ~100 km west of point P, this offset is small relative to the total wavelength of the above
anomalies and within the 150 to 300-km diameter suggested for intraplate hot spots [Epp, 1984; McNutt, 1989]. The correlation of MBA and bathymetry with basalt chemistry suggests that the along-axis density structure is closely related to the enriched material introduced by Galapagos plume beneath the ridge axis.

The final step in our gravity analysis is to remove the predictable effects due to lithospheric cooling. Calculation of the three-dimensional (3-D) distribution of temperature-dependent mantle densities for passive mantle upwelling is relatively simple using a standard method first presented by Phelps Morgan and Forsyth [1988]. We use a spectral method to solve for flow of a constant-viscosity mantle, driven by two spreading plates with the geometry of the Galapagos spreading center. Using finite difference approximations for the conductive-advective heat balance equation, we solve for steady state mantle temperatures, from which we derive mantle densities assuming a thermal expansion coefficient of $3.4 \times 10^{-5} \, ^\circ C^{-1}$. The integrated gravity fields from each density layer down to a 100-km depth represent the lithospheric cooling contribution to the gravity field [Kuo and Forsyth, 1988].

We subtract the lithospheric cooling effects from the MBA to produce the residual mantle Bouguer gravity anomaly (R MBA), shown in Plate 2c. The oval-shaped MBA low, observed between $-97^\circ W$ and $-85^\circ W$, is removed by the lithospheric cooling correction; what remain are high-amplitude negative anomalies branching from the ridge axis, over the Galapagos Archipelago and the Cocos and Carnegie Ridges. These negative R MBA branches reflect the anomalous volcanic and mantle density

---

Plate 2. (a) Contour and color-shaded map of the mantle Bouguer anomaly. Anomaly values $>20$ mGal are colored red, while those $<-120$ mGal are colored violet. Interpolated values between ship tracks are masked, and the spreading center and islands are marked in white. Note the oval-shaped negative anomaly aligned along the spreading center between $-97^\circ W$ and $-85^\circ W$ (outlined by the yellow shading) and the negative anomaly branches of the Cocos Ridge and Galapagos Archipelago. The five white profiles north of the spreading center mark isochrons from Wilson and Hey [1995] used for the off-axis analysis. Profiles are dashed in regions where magnetic lineations are extrapolated. (b) Mantle Bouguer gravity values extracted along the spreading center. Note that the anomalies reach a minimum at point P, where the ridge axis is closest to the hot spot. The arrows mark location of transform offsets. (c) Map of residual mantle Bouguer anomaly with contour interval of 20 mGal and a color range of -90 to +50 mGal. Note high-amplitude negative anomalies along the Cocos Ridge, the Darwin-Wolf seamounts, and the Galapagos Islands (shown in white). (d) Along-axis profile of residual mantle Bouguer anomaly showing $-100$ mGal decrease from the east and west toward point P. Arrows mark transform offsets.
Compensation of Topography

The mantle Bouguer correction has been widely used as a first-order correction for oceanic crustal structure [e.g., Kuo and Forsyth, 1988; Lin et al., 1990; Maden et al., 1990; Blackman and Forsyth, 1991; Morris and Detrick, 1991] since the total global variation in oceanic crustal thickness is ~3 km about a mean of 6 km [Chen, 1992]. Our assumption of a constant 6-km-thick crust is merely a first approximation of crustal structure from which we reference departures in density structure. Deviations from this reference model could be lateral variations in crustal thickness, lateral mantle density variations, or a combination of the two. The nonuniqueness of gravity solutions necessitates additional constraints. An obvious constraint is topography since, if in isostatic equilibrium, it too depends directly on density structure. Here we test two modes of isostatic compensation: (1) crustal compensation (Airy isostasy) and (2) compensation from lateral density variations in the mantle (Pratt isostasy).

Airy and Pratt Isostasy Admittance Functions

The theoretical mantle Bouguer gravity anomaly due to the two modes of isostatic compensation is solved using standard spectral methods as follows. In the spectral domain, the mantle Bouguer gravity anomaly B(k) is related to bathymetry H(k) by an isostatic response function, or admittance function Q(k), according to

\[ Q(k) = -2\pi G \varphi \left( \frac{1}{k z_p} - \frac{1}{k z} \right) \]

where k is the two-dimensional wavenumber, k = k_1k_2 = 2\pi/\lambda. Included in Q(k), are the effects of density structure that differs from the “reference” structure (i.e., a crust of uniform thickness overlying a mantle of uniform density). In Airy compensation models, it is the crustal structure that differs from the “reference” since topography is assumed to be supported by laterally varying crustal thickness. If we assume that elevated topography is supported by crust that is anomalously thick, the admittance function must include two terms to account for the effects at two interfaces as follows:

\[ Q(k) = -2\pi G [\Delta \rho \exp(-k z) + \rho_c \exp(-k z_c)] \]

where G = 6.67 x 10^{-11} m^3 kg^{-1} s^{-2} is Newton’s gravitational constant, \Delta \rho is the crust-mantle density contrast (500 kg/m^3), and \rho_c is the crust-water density contrast (1800 kg/m^3). The first term replaces the attraction of mantle by that of crust at the "reference" Moho (z_c = 8.7 is the average seafloor depth of 2.7 km plus 6.0 km). The second term accounts for the effects of the Airy crustal root at its assumed mean depth z_c of 11.0 km beneath the sea surface.

For Pratt compensation, it is mantle density that differs from the "reference" structure since topography is assumed to be compensated by laterally varying mantle densities. The amplitude of the density reduction in a vertical column required to support a given topographic elevation is \( H_p / z_c \), where \( H_p \) is the mantle-water density contrast (2300 kg/m^3) and \( z_c \) is the depth of compensation. The Pratt admittance function must therefore consider the integrated effects of all density layers from \( z_c \) to \( z_p \) and is thus defined as

\[ Q(k) = -2\pi G \varphi \left( \frac{1}{k z_p} - \frac{1}{k z_c} \right) \]

Results

Mantle Bouguer profiles taken along the present-day ridge axis and selected isochrons (Plate 2a) are compared with the Airy and Pratt theoretical profiles (Figure 2a). The standard deviation misfit between theoretical and observed profiles is plotted versus age (Ma). The locations of the off-axis crustal isochrons (labeled with ages from Wilson [1993]) are in Plate 2c. (b) The standard deviation misfit is plotted against crustal age for the five compensation models tested. Note that models of shallow depths of compensation yield the smaller misfits.
age in Figure 2b. For the crustal ages examined (0.0-7.67 Ma) the standard deviation misfit for the Airy compensation profiles has a nearly constant value of ~6 mGal, which is close to our estimated data uncertainty of 5.5 mGal. For the Pratt compensation models, standard deviation misfits increase with compensation depth ($z_p$) and with age. Along the present-day axis, the Pratt models of $z_p$=50 and 100 km are the most reasonable with standard deviations of 5.9 and 7.1 mGal, respectively.

Although the Airy profiles yield the lowest misfits to the observed MBA, the Pratt calculations with shallow compensation depths ($z_p$=50 and 100 km) also yield small misfits. Most of the misfit by the shallow Pratt calculations appears to be due to short-wavelength variations (<200 km) in the observed MBA which may come from local variations in crustal structure. We thus do not exclude the possibility that at least some of the gravity and topographic signal is due to density variations in the shallow mantle. The increase in misfits with age for the Pratt calculations may, however, reflect a decrease in the mantle contribution relative to that of the crust along paleoridge axes.

Topography may also be supported dynamically by lithospheric or upper mantle stresses. Previous work has shown that shallow stresses induced by plate spreading contribute significantly to axial topography [e.g., Phipps Morgan et al., 1987; Lin and Parmentier, 1989; Small and Sandwell, 1989; Chen and Morgan, 1990; Neumann and Forsyth, 1993]. Neumann and Forsyth [1993], for example, demonstrated that the correlation between gravity and topography along the Mid-Atlantic Ridge is due to dynamic stresses in the lithosphere which depend on crustal thickness and mantle thermal structure.

However, for the Galápagos spreading rates of 48-64 mm/yr and possible crustal thickness structure, these extension-related stresses would be small [Neumann and Forsyth, 1993]. Significant topography (>1 km) can also be maintained by viscous stresses in a convecting mantle [Anderson et al., 1973; McKenzie et al., 1980]. If viscous stresses are important along the Galápagos spreading center, they must be associated with low densities in the shallow mantle as indicated by our MBA modeling (Figure 2). We thus suggest that the long-wavelength topography of the Galápagos spreading center and nearby Cocos Plate is essentially isostatic and is supported by density anomalies primarily within 100 km beneath the seafloor.

**Present-Day Axial Mantle Temperatures**

As demonstrated above, crustal thickness and shallow mantle density variations are both likely sources of topographic compensation. We suggest that they both occur and that both are controlled by mantle temperature: crustal thickness by temperature-enhanced melting, and mantle density by thermal expansion. For the following analysis, we investigate the mantle temperature variation required to generate the -90-mGal variation in along-axis MBA and the ~1.1-km increase in axial topography.

**Model Configuration**

Using the same numerical methods as were used for the lithospheric cooling calculations, we solve for 3-D mantle temperatures due to passive upwelling; this time, however, we impose a temperature anomaly $\Delta T$ at the base layer (Figure 3). To estimate the additional crust that may result from a given $\Delta T$, we take the fraction of partial melting $f_p$ to depend on mantle temperature $T$ by $f_p=\frac{(T-T_s)}{600^\circ}$, where $T_s$ is the mantle solidus and 600°C is the supersolidus temperature required to fully melt a unit volume of peridotite [Reid and Jackson, 1981]. The rate of melt generation $f$ depends on the gradient of $f$ and mantle flow rate $v$ by $f=\nu\frac{\partial f}{\partial T}$ [Reid and Jackson, 1981]. We estimate the mantle solidus to be linearly dependent on pressure and thus depth $z$ (in kilometers below the seafloor), by $T_s=1100^\circ C+3.25(\text{C/km})$. Crustal accretion at the ridge crest depends on the spatial distribution of melting and subsequent migration of melt toward the ridge. The process of melt migration is still largely unconstrained; therefore we simplify this calculation by treating ridge segments as line sinks which draw in melt from the mantle below [Phipps Morgan and Forsyth, 1988]. Assuming that melt migrates over a finite lateral extent, we define a width $\delta$, on each side of the ridge axis, as the region of melt transport (Figure 3); outside of this melt transportation zone, we assume that melts are carried away by the cooling lithospheric plates thus do not contribute to the crust. We also assume that a small melt fraction $f_m$ is retained in the mantle matrix within this zone of melt transport. We adjust the parameters $\delta$ and $f_m$ such that the resulting crustal thickness for a normal base layer temperature (1350°C) is 6 km at the ridge segment centers. This result is achieved for $f_m$ values of 0-6% [Forsyth, 1992] and corresponding $\delta$ values of 30-50 km. We assume that $f_m$ does not vary along-axis therefore it does not contribute to the long-wavelength variation in mantle density. The base layer is set to a depth of 160 km to ensure that the entire melting region is included.

**Base Layer Temperature Distributions**

For the base layer temperature anomalies, we investigate three geometries. In our first set of calculations (model A), we vary temperatures linearly along-axis with the maximum anomaly beneath the 91°W transform (Figure 4a). This is the simplest model, designed to test the effects of strictly along-axis variation in temperatures. For the second set of calculations (model B), we impose a circular anomaly centered on the island Fernandina, thought to mark the current location of the Galápagos hot spot center [White et al., 1993] (point H, Figure 4b). Temperatures decrease linearly away from point H. We envision this model to represent the temperature distribution from a radial dispersion of plume material from the hot spot center. For the third set of
results of model A for different base layer temperature anomalies at point P (ΔTc) with observed MBA and bathymetry profiles. Profile sections near transform faults are omitted since our models gave unrealistically small crustal thicknesses due to local cooling effects near ridge segment ends. Removal of these local effects, however, do not affect the larger-scale thermal anomaly related to the Galápagos hot spot.

As illustrated in Figures 5a and 5b, the model for ΔTc of 50°C best fits both the MBA and bathymetry profiles. The ΔTc=25 and 75°C solutions are the upper and lower limits for model A. Table 1 outlines the corresponding results of models B and C and the associated standard deviation misfits. Despite differences in the detail 3-D temperature structure between the three models, all three suggest similar values of ΔTc with comparable minimum misfit. This finding indicates that axial crustal and density structure is sensitive primarily to temperatures directly beneath the ridge axis and insensitive to subtle temperature changes away from the ridge axis. We conclude ΔTc to be -50±25°C with a corresponding crustal thickening of 3±1 km (Figure 5c). As the crust thickens toward point P, it gives rise to 70-75% of the topographic swell and MBA gravity signal. The remaining 25-30% of topography and gravity signal is supplied by the anomalously hot and less dense mantle beneath the ridge axis.

Results

Gravity calculations for the three models are done by applying Parker’s [1973] method to the density layers in the mantle and the crust-mantle interface treating the crustal thickness as only varying along-axis. Since we have shown that the long-wavelength seafloor topography is compensated at shallow-depths, we calculate theoretical bathymetry assuming Airy compensation for the crust and Pratt compensation for the mantle shallower than 160 km. Figures 5a and 5b compare theoretical results of model A for different base layer temperature anomalies at point P (ΔTc) with observed MBA and bathymetry profiles. Profile sections near transform faults are omitted since our models gave unrealistically small crustal thicknesses due to local cooling effects near ridge segment ends. Removal of these local effects, however, do not affect the larger-scale thermal anomaly related to the Galápagos hot spot.
Our crustal model is consistent with estimates of Feighner and Richards [1994] based on flexural modeling of gravity near the Galápagos Archipelago. Confirming this crustal model, however, requires future marine seismic experiments since few seismic constraints exist to date.

Discussion

Our primary focus in this study is the effects of mantle temperature on crustal thickness and on mantle density changes by thermal expansion. A number of factors not incorporated into our models may also contribute to crustal thickness and mantle density structure and lead to changes in our $\Delta T_p$ estimate. These include (1) compositionally dependent and disequilibrium melting, (2) melt depletion and latent heat loss in the mantle, (3) buoyancy-driven mantle flow, and (4) mantle compositional effects on melting and on mantle densities. We briefly discuss these factors below.

Compositionally dependent and disequilibrium melting.

The simple linear melt function and linear depth-solidus relation that we used was defined by Reid and Jackson [1981] based on results of batch melting experiments in which melt maintained equilibrium with the remaining solid phases. If melt is extracted rapidly in the mantle such that it fails to equilibrate with the matrix, then the solidus of the depleted residue increases with increasing melt extents [Kinzler and Grove, 1992; Cordery and Phipps Morgan, 1993]. If this disequilibrium melting scenario is the dominant process in the mantle, then a greater $\Delta T_p$ than we estimated may be required beneath the Galápagos spreading center to thicken the crust by 3±1 km.

Melt depletion and latent heat loss in the mantle.

In addition to inhibiting melting, melt depletion may also reduce
mantle densities, primarily by decreasing the Fe/Mg ratio of the residue [Oxburgh and Parmentier, 1977]. The opposite effect, however, may result from latent heat removal which cools the mantle thus increases its density. Numerical experiments by Magde et al. [1995] indicate that to generate an oceanic crust of normal thickness, the two factors would lead to a net decrease in mantle densities of the order of 1%, or ~6 times the thermal expansion effect of heating the mantle by 50°C. This potential density reduction may contribute to the Galapagos bathymetry and gravity anomalies significantly enough that the crustal thickness and thus $\Delta T_p$ are smaller than we estimated.

**Buoyancy-driven mantle flow.** In addition to their direct signature on surface observables, mantle density variations lead to buoyancy forces which drive mantle flow. Beneath normal oceanic spreading centers the dominant sources of buoyancy are most likely melt depletion-related and melt retention-related density reductions [Jha et al., 1994]. If buoyancy forces are important, they are likely to enhance vertical flow and increase the rate of melting and thus may lead to a lower $\Delta T_p$ prediction.

**Mantle compositional effects on melting and on mantle densities.** A hot spot-related temperature anomaly as investigated in this study is an obvious source for thickened crust and reduced mantle densities; however, mantle source heterogeneity may also play important roles. Enrichment in volatile [Bonati, 1990] or incompatible elements [Michael et al., 1994] in the mantle may enhance melting and thus yield a thicker crust for a given mantle temperature anomaly. While there is little evidence for a volatile enrichment beneath the Galapagos spreading center, there is evidence for an increase in incompatible element concentration toward point P from ridge axis samples [Schilling et al., 1982; Langmuir et al., 1992]. In addition, a decrease in Fe/Mg was observed in axial samples toward point P [Schilling et al., 1982; Langmuir et al., 1992], possibly reflecting a low Fe/Mg and thus low-density mantle source near the Galapagos hot spot. Including such heterogeneities of the mantle source in incompatible element content and Fe/Mg ratio may yield a lower $\Delta T_p$ estimate.

In summary, while considering factors 1 would increase an estimate of $\Delta T_p$, considering factors 2, 3, and 4 would substantially decrease an estimate of $\Delta T_p$. We therefore anticipate that our estimate of $\Delta T_p$ is an upper bound, although the interplay of the above four factors may be complex and requires comprehensive investigation that is beyond the scope of this study.

By considering the first-order aspects of mantle flow, heat transport, and decompression melting, we have established a relation between crustal thickness, temperature-dependent mantle density, and mantle temperature anomaly. Our approach is consistent with previous studies of intraplate hot spot anomalies. For example, Crough [1978], Sleep [1990], and McNutt [1987] constrained hot spot temperature anomalies based on mantle-density anomalies which they took to be strictly temperature dependent. McKenzie [1984] constrained hot spot anomalies based on estimates of crustal thickness assuming, as we do, that melting occurs under equilibrium conditions. Our relationship between $\Delta T$ and the mantle component of topography is essentially the same as Sleep's [1990], and our relationship between $\Delta T$ and crustal thickness is consistent with that of McKenzie [1984] (50-75°C for crustal thickening of 2-4 km).

Our constraints on $\Delta T$ beneath the Galapagos spreading center have implications for the nature of heat transport both along the ridge axis and from the hot spot to the ridge axis. Using Feighner and Richard's [1994] estimate for the volcanic thickness of the Galapagos Archipelago (15-20 km) and McKenzie's [1984] melting relationships, we estimate a temperature anomaly of ~200°C at the hot spot center (point H, Figure 6). This temperature estimate is similar to the 214°C anomaly estimated by Schilling [1991] based on buoyancy flux arguments. Considering our upper (75°C) and lower (25°C) estimates for the temperature anomaly at point P, the average gradient from the hot spot to the ridge axis (H to P, Figure 6) is 0.74-1.03°C/km. In contrast, the along-axis gradient is only 0.04-0.11°C/km. Therefore any successful models of sublithospheric plume dispersion must yield an along-axis temperature gradient that is an order of magnitude less than that from the hot spot to the ridge axis. Rigorous investigation of this question requires further experimental [Kincaid, 1994] and numerical [Rowley et al., 1992] work.

**Paleoaxial Temperature Anomalies**

To better constrain the temporal evolution of the Galapagos ridge-hot spot system, we next examine MBA and bathymetry anomalies along paleoaxes of the Galapagos spreading center. From our model calculations we derive empirical relations between $\Delta T$ and MBA and bathymetry that we then use to estimate past temperature anomalies from the observed amplitudes of along-isochron MBA and bathymetry anomalies. In order to apply relationships derived from the active spreading center to off-axis anomalies, we must make two assumptions. First, we assume that any off-axis crustal accretion on the Cocos Plate is insignificant and that the spreading rate has not changed significantly over the past 7.7 m.y. Second, we assume the

![Figure 6. Map of the Galapagos region marked with estimated base layer temperature anomalies at various points along the ridge axis (solid line) and at the hot spot center (point H). Arrows point in the direction of decreasing temperature anomalies from the hot spot to ridge-axis (arrow 1) and along the ridge axis (arrow 2). Estimated temperature gradients in both directions are labeled. Note that gradient 1 is 10-20 times greater than gradient 2.](image)
observed MBA and bathymetry along isochrons are due primarily to the crustal structure that was frozen into the lithosphere at the time of accretion.

Our linear melting function yields an essentially linear relation between $\Delta T$ and MBA and bathymetry. This relation is derived empirically by a least squares fit between theoretical values of MBA and bathymetry and corresponding values of base layer $\Delta T$ for model A calculations. Only points further than -80 km from transform offsets are used in the fit. The dependence of $\Delta T$ on MBA is found to be

$$\Delta T = 0.5766 \Delta \text{MBA}$$

with a < 3°C standard deviation misfit to model calculations. The dependence of $\Delta T$ on depth anomaly $\Delta H$ is found to be

$$\Delta T = 48.3 \Delta H$$

with a < 5°C standard deviation misfit to model calculations.

Using the peak mantle Bouger and bathymetry anomalies along each isochron, we derive peak temperature anomalies beneath paleospreading centers (Figure 7). Along the 7.7 Ma isochron the observed MBA is -150 mGal, and bathymetry

![Figure 7](image_url)

Figure 7. The empirical relationships between base layer temperature anomaly and (a) MBA and (b) bathymetry anomaly (solid lines). Also plotted are derived $\Delta T$ values for maximums in observed MBA and bathymetry along crustal isochrons (dots). Errors in gravity (12 mGal) and bathymetry (0.3) are the estimated variations due to ridge segmentation, while errors in $\Delta T$ are ±25°C, as defined according model A results.

![Figure 8](image_url)

Figure 8. (a) Peak base layer $\Delta T$ calculated from MBA (circles) and bathymetry anomalies (triangles) along selected isochrons are plotted against the isochron ages. The solid line marks $\Delta T$ averaged between the gravity and bathymetry calculations. The uncertainty of ±25°C in $\Delta T$ is the uncertainty estimated from results for the present-day ridge axis. (b) Map showing the Galápagos hot spot and the locations of peak temperature anomalies along the present and paleoaxes of the Galápagos spreading center. The 3.0-, 2.0-, and 1.0-km depth intervals are contoured, and the ridge axis is marked as a bold solid line.
anomaly is \(-1.7\) km; these anomalies yield a past temperature anomaly of \(-86\text{-}88^\circ\text{C}\), 70\% greater than the anomaly along the present-day ridge axis. As shown in Figure 8a both MBA (circles) and bathymetry (triangles) relationships produce consistent temperature anomalies.

Also illustrated in Figure 8a is the decrease in amplitudes of the MBA and bathymetry anomalies with decreasing isochron age. This behavior indicates that the peak temperature anomaly beneath the Galápagos spreading center has steadily decreased since 7.7 Ma, when the hot spot was at or near the ridge axis. As the hot spot migrated southwest away from the ridge axis beneath the Nazca Plate, the maximum in \(\Delta T\) decreased and the axial position of the peak in \(\Delta T\) moved westward at approximately the same rate as the westward velocity component of the hot spot with respect to the Cocos Plate (Figure 8b). If we assume that the thermal anomaly of the hot spot has remained constant over the past \(-8\) m.y., the above results provide evidence that the amplitude of temperature anomaly beneath the Galápagos ridge axis is a function of the distance separating the hot spot and ridge axis. Such a dependence may reflect the cooling of plume material as it migrates from the Galápagos hotspot to the ridge axis and may provide important constraints on the mechanisms of heat transfer between hot spots and nearby ridges.

**Conclusions**

The 2-D pattern of the mantle Bouger and bathymetry anomalies reflect temperature-dependent density structure imposed by the Galápagos hot spot. Correlation of MBA and bathymetry with geochemical anomalies supports the notion of mixing of a hot, enriched plume with the cooler, depleted upper mantle. Profiles of mantle Bouger gravity anomalies taken along isochrons of ages 0.0-7.67 Ma indicate that long-wavelength topography is isostatically compensated by density structure in the crust and upper 100 km of the mantle. To account for the \(-90\) mGal along-axis decrease in MBA and the \(-1.1\) km decrease in depth, our models require a subaxial temperature anomaly of \(+0.25^\circ\text{C}\) and an associated crustal thickness increase of \(+2\) km. Mantle temperatures decrease dramatically from the hot spot to the ridge axis but decrease much more gradually along axis with a lateral temperature gradient 10-20 times less. This contrast places important constraints on hot spot-to-ridge and along-ridge heat transport.

From the crustal isochron of age 7.7 Ma to the present-day axis, the along-isochron amplitudes of MBA decrease from \(-150\) to \(-90\) mGal. The corresponding along-isochron bathymetry anomalies decrease from \(-1.7\) to \(-1.1\) km. These MBA and bathymetry anomalies indicate that the axial temperature anomaly was \(+70^\circ\text{C}\) hotter in the past (86\text{-}88\(^\circ\text{C}\)) and has steadily decreased to \(+0.25^\circ\text{C}\) as the ridge axis migrated away from the Galápagos hot spot. The simplest explanation for this apparent decrease in the mantle anomaly beneath the Galápagos spreading center since 7.7 Ma is that the ridge axis temperature structure depends on the distance separating the hot spot and ridge axis. These conclusions point to the need for further experimental and numerical investigations to better understand the dynamic interaction between the Galápagos spreading center and hot spot and the effects of such interactive processes on the internal structure of the oceanic lithosphere.

**Acknowledgments.** This project was inspired by discussions with Mary Kleinrock, who also assisted in locating the Galápagos ridge-axis coordinates. We are grateful for helpful discussions with Robert Detrick, Stan Hart, and Marcia McNutt and for reviews by Gregory Neumann, John Madsen, Jean-Guy Schilling, and Norm Sleep. Douglas Wilson supplied the Cocos Plate isochron coordinates: Jasen Phipps Morgan supplied the high-density gravity and bathymetry data near 95\(^\circ\text{W}\); and Marcia McNutt assisted with funding. This work was supported by NSF grants OCE9020408 and OCE9302915 and ONR grant N00014-91-J-1433.

ABSTRACT
We analyzed bathymetric and gravity anomalies along present and paleoaxes of oceanic spreading centers influenced by the Iceland, Azores, Galápagos, Tristan, and Easter hotspots. Residual bathymetry (up to 4.7 km) and mantle Bouguer gravity (up to −340 km) anomalies are maximum at on-axis hotspots and decrease with increasing ridge-hotspot separation distance (D), until becoming insignificant at D ~ 500 km. Along-isochron widths of bathymetric anomalies (up to 2,700 km) depend inversely on paleo–spreading rate, reflecting the extent to which plume material will flow along axis before being swept away by the spreading lithosphere. Flux balance arguments suggest that the five hotspots feed material to ridges with comparable fluxes of ~2.2 × 10⁶ km²/My. Assuming that the amplitudes of these geophysical anomalies reflect temperature-dependent crustal thickness and mantle density variations, we suggest that ridge temperature anomalies are maximum (150–225 °C) when plumes are ridge centered and decrease with increasing ridge-hotspot distance due to cooling of the ridgeward-migrating plume material.

INTRODUCTION
When mantle plumes rise near oceanic spreading centers, they generate not only near-ridge hotspots, but also melt anomalies at the axis of the nearby ridges (e.g., Morgan, 1978). Direct evidence that near-ridge plumes divert toward and feed ridges is the ocean-island basalt (OIB) geochemical signature in ridge basalts (e.g., Hart et al., 1973). Furthermore, along-axis gradients in the strength of OIB signatures and in topography (e.g., Vogt, 1976; Schilling, 1991) indicate that once a plume reaches a ridge, it spreads laterally along axis.

Previous studies of ridge-plume interactions have focused primarily on present-day spreading centers. Ito and Lin (1995), however, demonstrated that 70–75% of off-axis bathymetric and gravity anomalies of the Cocos plate can be attributed to the anomalous crustal thicknesses generated at the paleo-Galápagos ridge axis. We attributed long-wavelength (>200 km) variations in bathymetry and gravity along crustal isochrons to temperature conditions beneath the hotspot-influenced ridge axis at the time the crust was created.

In this study we investigated the evolution of five prominent plume-ridge systems over wide ranges in ridge-hotspot separation distance and spreading rate. The results of this study provide observational constraints on the amplitudes of along-isochron bathymetric and gravity anomalies as they depend on ridge-hotspot separation distance, and along-isochron widths of bathymetric anomalies as they depend on ridge spreading rate.

ALONG-ISOCHEM BATHYMETRIC AND GRAVITY ANOMALIES
Iceland, Azores, Tristan, Galápagos, and Easter (Fig. 1) are the five hotspots that impose the most prominent bathymetric and geo-

![Figure 1. Regional bathymetric maps (mercator projections) of five prominent hotspot-ridge systems: Iceland, Azores, and Tristan, near Mid-Atlantic Ridge; Galápagos, near Galápagos spreading center; and Easter, near East Pacific Rise. Etopo5 (Earth topography at 5 minute grid spacing, National Geophysical Data Center Report MGG-5) bathymetry points within 5 min of ship data points were omitted before gridding at 5 min grid spacing. Circles mark present-day locations of hotspots; solid lines mark ridge axes and off-axis isochrons along which data profiles were taken. To exclude sea floor affected by off-axis volcanism we used isochrons of ages 0–30 Ma for Iceland and 0–25 Ma for Azores on North American plate; 0–8 Ma for Galápagos on Cocos plate; and 0–20 Ma for Easter on Pacific plate. For Tristan, we used isochrons of ages 0–70 Ma on South American plate and ages 80–110 Ma on African plate because hotspot crossed from South American to African plate at ~60 Ma (O’Connor and Duncan, 1990).](image-url)
chemical anomalies observed at nearby oceanic spreading centers (Hart et al., 1973; Hamelin et al., 1984; Schilling, 1985). Encompassing each of the five systems, we obtained shipboard bathymetric data from the National Geophysical Data Center (NGDC) and Lamont-Doherty Earth Observatory (LDEO), and gridded bathymetry from NGDC. To derive residual bathymetry, we first corrected the raw data for isostatic effects of sediment loading and then subtracted predicted depths of a cooling mantle half space (Carlson and Johnson, 1994). Sediment thicknesses were obtained from the LDEO database (A. Cazenave, Centre National d'Etudes Spatiales, Toulouse, France), and density contrasts between the sediments and mantle, and mantle and water were assumed to be 1600 kg/m³ and 2300 kg/m³, respectively. Free-air gravity data were taken from the ship surveys and the satellite altimetry-derived gravity grid of Sandwell and Smith (1992). To isolate the effects of sub-sea-floor density structure, we generated mantle Bouguer anomalies by subtracting from the free-air gravity the attractions of the sea-floor-water (density contrast, $\Delta\rho = 1800$ kg/m³) and crust-mantle ($\Delta\rho = 500$ kg/m³) interfaces using raw bathymetry, and assuming a crust of uniform thickness (6.5 km) (e.g., Kao and Forsyth, 1988).

Coordinates of present-day ridge axes and crustal isochrons were defined by using plate boundary and age data of Muller et al. (1993a). Because our focus was on anomalies generated at the axes of spreading centers, we considered only data from sea floor unaffected by off-axis volcanism, as detailed in the Figure 1 caption. From our residual bathymetry and mantle Bouguer grids, we then extracted along-isochron profiles (Fig. 2).

ANOMALY AMPLITUDES VS. PALEO-SPREADING RATE

To determine hotspot locations relative to paleo-spreading centers, we assumed that the hotspots were stationary with respect to each other and used plate-reconstruction poles (Lonsdale 1988; Müller et al., 1993b) to rotate isochrons with respect to the hotspots back to their positions at the time of accretion. We then measured distances between the paleo-ridge axes and hotspot centers, which we took to be the locations of most recent volcanism.

The along-isochron variations in residual bathymetric ($\Delta RB$) and mantle Bouguer anomalies ($\Delta MBA$) display a decrease with increasing paleo-ridge-hotspot distance ($D$, Fig. 3). The on-ridge hotspots (Cases I, 50 km for the Tristan system (80–90 Ma isochrons) and the Iceland system (0–30 Ma) display the highest $\Delta RB$ (3.5–4.7 km) and most negative $\Delta MBA$ (~250 to ~340 mgal), which are approximately twice those of ridge-centered cases for the Galápagos and Azores systems. At $D > 500$ km, the hotspot signals become very weak and in the case of Tristan, become indistinguishable from normal ridge-segmentation-related variations. The individual Galápagos and Tristan systems show a decrease in $\Delta RB$ and $\Delta MBA$ with increasing $D$, whereas the Azores system is more complex and the Easter trend is very weak. The predominant decrease of $\Delta RB$ and $\Delta MBA$ with increasing $D$ is consistent with Schilling’s (1985) study of present-day ridge-axis bathymetry.

ANOMALY WIDTHS VS. PALEO-SPREADING RATE

Whereas amplitudes of $\Delta RB$ and $\Delta MBA$ are functions of ridge-hotspot distance, along-isochron widths ($W$) of the bathymetric anomalies (see Fig. 2 caption) depend primarily on the full spreading-rate ($U$) at the time of crustal accretion. The maximum values of $W$ are found along the slowest-spreading Mid-Atlantic Ridge near Iceland (2700 km, Fig. 4A); these values are comparable to the long-axis extent of the helium isotope anomaly, but are a factor of two greater than the widths of rare-earth-element anomalies (Schilling, 1986). Values of $W$ decrease with increasing $U$ to a minimum along the fast-spreading East Pacific Rise.

The observed dependence of $W$ on spreading rate lends strong support to previous notions of along-axis plume material flow (Vogt, 1976; Schilling, 1985). Similarly to Schilling (1991), we estimate that the flux of plume material feeding the ridge ($Q$) is eventually carried away by the spreading lithospheric plates (Fig. 4A, inset), such that

$$Q = \int_{-w_2}^{w_2} P(y)hU dy = \frac{hUW}{2},$$

where $y$ is the along-axis coordinate, $h$ is the thickness of the fully developed lithosphere (assumed to be 80 km), and $P(y)$ is the percentage of accreted lithosphere derived from the plume material assumed to decrease linearly from 1 at $y = 0$ to 0 at $y = \pm W/2$.

We treat the hotspot to ridge flow as a simple laminar flow problem in which the lithospheric drag opposes the ridgeward flow of plume material. The channel connecting the ridge and hotspot has a characteristic width $w_2$ and thickness $w_1$ (see Fig. 4 A and B, insets). Therefore, the net flux from the hotspot to the ridge is

$$Q = \frac{w_1 w_2}{hU} \left( V - \frac{U}{4} \right),$$

where $V$ is the average ridgeward velocity of plume flow, $w_1 w_2 V$ is the ridgeward flux, and $w_1 w_2 U/4$ is the opposing plate-driven flux. Combining equations 1 and 2 yields the dependence of $W$ on spreading rate,

$$W = \frac{2w_1 w_2}{hU} \left( \frac{V}{4} - \frac{U}{4} \right).$$

The solid curve in Figure 4A is that predicted for assumed values of $V = 70$ km/m.y. and $w_1 w_2 = 3 \times 10^7$ km², which yields a root-mean-square misfit to the data of 500 km. Similar misfits are achieved for $V = 30$–100 km/m.y. and corresponding values of $w_1 w_2$ of 8–2 $\times 10^4$ km². These results suggest that the ridgeward fluxes from the five

GEOLOGY, July 1995

38
hotspots are comparable, the average value being $\sim 2.2 \times 10^7$ km$^3$/m.y. Increasing or decreasing $V_{r,0}$ by $1 \times 10^5$ km$^3$/m.y. increases the data misfit by a factor of two.

Our theoretical relation between $W$ and $U$ is based on one end-member scenario in which lateral spreading of plume material beneath ridges is strictly ridge parallel. A numerical study that considers both ridge-parallel and ridge-perpendicular spreading of plumes beneath ridges (Feighner et al., 1995) may represent the other end member; it thus predicts that $W$ is proportional to $(U/U_0)^{1/2}$ rather than $(U/\bar{U})$, as does our model.

**PALEO-RIDGE-AXIS TEMPERATURE ANOMALIES**

We show here how the amplitudes of $\Delta RB$ and $\Delta MBA$ may reflect the temperature anomalies beneath the paleo-ridge axes. We assume that $\Delta RB$ and $\Delta MBA$ arise from crustal-thickness and mantle-density anomalies, both of which depend on the ridge-axis temperature anomaly at the time of crustal accretion. $\Delta RB$ and $\Delta MBA$ can be related to a hotspot-induced mantle temperature anomaly ($\Delta T$) using the model of Ito and Lin (1995), which considered changes in mantle density by thermal expansion, and in crustal thickness by increased decompression melting. Assuming passive mantle upwelling, Ito and Lin (1995) imposed temperature anomalies below the melting zone and then combined the effects of crustal-thickness and mantle-density variations to yield theoretical isostatic bathymetric variations and $\Delta MBA$.

Applying this method for ranges of imposed temperature anomalies and model spreading rates, we derive the empirical relations:

$$\Delta T = (0.11U + 35.3)\Delta RB,$$

and

$$\Delta T = (0.0017U + 0.45)\Delta MBA.$$

(5)

The dependence of $\Delta T$ on $U$ reflects a subtle dependence of crustal thickness on spreading rate that is consistent with calculations of Su et al. (1994). For $\Delta T = 100$ °C and $U = 20$–$100$ km/m.y., for example, we predict corresponding values of crustal thickening of 9–4.5 km.

Temperature anomalies derived accordingly from the observed $\Delta RB$ and $\Delta MBA$ are maximum for the on-ridge cases (150–225 °C), and decrease to near zero for $D = 500$ km (Fig. 4B). Such a behavior can be interpreted as the cooling trend of plume material as it migrates from hotspot centers to nearby ridges, the ridge-centered cases reflecting the temperature anomaly of the hotspot itself.

As plume material migrates from a hotspot center to a ridge, it conducts heat to the surrounding mantle (see Fig. 4, A and B, insets). Assuming that the amount of heat conducted in the direction of plume flow is negligible, the heat balance equation is
\[ \frac{\partial T}{\partial t} = \frac{\kappa}{\rho c_p} \left( \frac{\partial q_1}{\partial y} + \frac{\partial q_2}{\partial z} \right), \]

where \( T \) is the average temperature of the plume conduit, \( \rho \) and \( c_p \) are the density and heat capacity of the plume material, respectively, and \( q_1 \) and \( q_2 \) are the components of convective heat flow out of the conduit walls. If we assume that heat loss occurs through a thermal boundary layer surrounding the plume channel with thickness \( \delta \),

\[ q_1 - q_2 \sim -\frac{\kappa \Delta T}{\delta}, \]

where \( k \) is the mantle thermal conductivity (3 W m\(^{-1}\) K\(^{-1}\)) and \( \delta \) is defined such that \( q = 30-100 \) mW m\(^{-1}\), comparable to heat-flux values on the sea floor. If it is assumed that the gradients \( \partial q_1/\partial y \) and \( \partial q_2/\partial z \) are proportional to \( 1/w_1 \) and \( 1/w_2 \), respectively, and \( q \sim w_1w_2V \) (i.e., \( V \gg \mu/4 \)), the combination of equations 6 and 7 yields

\[ \frac{\partial T}{\partial t} = -\frac{2k}{\rho c_p} (w_1 + w_2) \Delta T, \]

where \( \kappa = k/(\rho c_p) \) is thermal diffusivity (10^{-6} m\(^2\) s\(^{-1}\)). Integrating with respect to \( x \) from 0 to \( D \) yields

\[ \Delta T = \Delta T_0 \exp \left( -\frac{2k}{\rho c_p} (w_1 + w_2) D \right), \]

where \( \Delta T_0 \) is the temperature anomaly at the hotspot center.

CONCLUSIONS

Along-isochron variations in residual bathymetry and mantle Bouger gravity reflect the influence of hotspots on paleoaxes of nearby spreading centers. The amplitudes of along-isochron anomalies for the five prominent plume-ridge systems reach a maximum ridge-hotspot distance of 2700 km, however, depend inversely on paleo-spread rate. Whereas the widths of \( \Delta RB \) reflect the balance between ridgeward plume flux and lithospheric accretion, the amplitudes of \( \Delta RB \) and \( \Delta MBA \) reflect paleoaxial temperature anomalies that decrease as the plume material cools along its lateral migration to nearby ridges. The five hotspots appear to deliver material to ridges with comparable fluxes of \( 2.2 \times 10^{5} \) m\(^3\) km\(^{-1}\) y\(^{-1}\) and produce excess mantle temperature anomalies of 50 to 225 °C that influence ridge-axis structure to a maximum ridge-hotspot distance of ~500 km.

CHAPTER 3

DYNAMICS OF MANTLE FLOW AND MELTING AT A RIDGE-CENTERED HOTSPOT: ICELAND AND THE MID-ATLANTIC RIDGE
Abstract

We investigate the dynamics of mantle flow and melting of a ridge-centered plume with three-dimensional variable-viscosity numerical models, focusing on three buoyancy sources: temperature, melt depletion, and melt retention. The width \( W \), to which a plume spreads along a ridge axis, depends on plume volume flux \( Q \), full spreading rate \( U \), buoyancy number \( B \), and ambient/plume viscosity contrast \( \gamma \). When all melting effects are considered, our numerical results are best parameterized by \( W = 2.37(Q/U)^{1/2}(B\gamma)^{0.04} \). Thermal buoyancy is first order in controlling along-axis plume spreading while latent heat loss due to melting, and depletion and retention buoyancy forces contribute second-order effects. We propose two end-member models for the Iceland plume beneath the Mid-Atlantic Ridge (MAR). The first has a broad plume source with temperature anomaly \( \Delta T_p \) of 75°C, radius \( a \) of 300 km, and \( Q \) of \( 1.2 \times 10^7 \) km\(^3\)/my. The second is of a narrower and hotter plume source with \( \Delta T_p \) of 170°C, radius of 60 km, and \( Q \) of \( 2.1 \times 10^6 \) km\(^3\)/my. The broad plume source predicts successfully the observed seismic crustal thickness, topographic, and gravity anomalies along the MAR, but predicts an along-axis geochemical plume width substantially broader than that suggested by the observed Sr\(^{87}/\text{Sr}^{86} \) anomaly. The narrow plume source model predicts successfully the total excess crustal production rate along the MAR (\( 2.5 \times 10^9 \) km\(^3\)/my) and a geochemical width consistent with that of the Sr\(^{87}/\text{Sr}^{86} \) anomaly, but it requires substantial along-axis melt transport to explain the observed along-axis variations in crustal thickness, bathymetry, and gravity. Calculations suggest that lateral plume dispersion may be radially symmetric rather than channeled along the ridge axis and that the topographic swell, which is elongated along the Reykjanes Ridge, may be due to rapid off-axis subsidence associated with lithospheric cooling.
superimposed on a broader hotspot swell. The two plume source models predict seismic P-wave velocity reductions of 0.5-2% in the center of the plume, producing travel time delays of 0.2-1.2 s. Predicted P-wave delay-times for the narrow plume source model are more consistent with recent seismic observations beneath Iceland, suggesting that this model may be more representative of the Iceland plume.

1. Introduction

Centered on the Mid-Atlantic Ridge (MAR), the Iceland hotspot is the largest melt anomaly throughout the world’s mid-ocean ridge system and is among the large oceanic igneous provinces [1]. The idea that Iceland marks a mantle convection plume rising beneath the MAR has become well established since its original conception in the early 1970’s (e.g. ref. [2, 3, 4]). The broad topographic swell (Fig. 1) and correlated along-spreading-axis geochemical anomalies indicate that the plume rises beneath Iceland and spreads laterally along the ridge axis [4, 5]. Such along-axis spreading of a mantle plume feeding a ridge axis may also explain topographic and geochemical anomalies affected by other near ridge-axis hotspots (e.g. ref [6, 7, 8])—many of which may have contributed substantially to the earth’s heat and magmatic budget throughout geologic history.

While the original concept that plumes feed and spread along nearby ridges was proposed two decades ago, only recently have the fluid dynamic aspects been investigated quantitatively. Recent numerical and laboratory tank experiments have shown that the width $W$, over which a plume spreads along axis, increases with plume volume flux $Q$, and decreases with plate full-spreading rate $U$ [9, 10, 11]. Such studies are important in revealing the pertinent physical processes governing plume-ridge interactions and in placing theoretical constraints on properties of mantle plumes such as temperature anomaly, size, and volume flux.

Two potentially important sources of buoyancy, however, have not been considered in previous plume-ridge studies. These are melt depletion, which lowers the Fe/Mg ratio in the residual mantle and thus reduces its density [12], and melt retention in the mantle, which also reduces mantle bulk density (e.g. [13, 14, 15]). It has been proposed that melt depletion may be primary in driving spreading of intraplate plumes beneath the lithosphere [16]. It has also been proposed that both melt retention buoyancy and depletion buoyancy may contribute significantly to along-axis variations in mantle flow and crustal thickness beneath normal mid-ocean ridges [17, 18].
The objectives for this study are two fold. First we investigate numerically the effects of thermal- and melting-related buoyancy forces on along-axis spreading of ridge-centered plumes. We use three-dimensional (3D), variable viscosity, numerical models to simulate a buoyant plume rising beneath spreading plates and systematically test the effects of thermal, melt depletion, and melt retention buoyancy forces. Our second objective is to constrain the temperature anomaly, dimension, and volume flux of the Iceland plume by comparing theoretical predictions with observed variations in seismic crustal thickness, topography, gravity, and geochemistry on Iceland and along the Mid-Atlantic Ridge. We propose two end-member models for the mantle plume source beneath Iceland to explain the observations, and discuss their implications on basalt geochemistry, melt migration, and seismic velocity variations along the Mid-Atlantic Ridge axis.

2. Governing equations

To model mantle flow of a plume-ridge system in the upper-mantle, we treat the mantle as a fluid of zero Reynolds number and infinite Prandtl number. The 3D stress tensor, $\tau$, is defined according to

$$\tau = 2\eta(T_R, \rho) \dot{\varepsilon} - p I \quad (1)$$

where $I$ is the identity matrix and $\eta$ is viscosity which depends on real temperature $T_R$ and hydrostatic pressure $p$. The strain rate tensor $\dot{\varepsilon}$ depends on spatial derivatives of mantle flow rate $u$ according to $\dot{\varepsilon} = 1/2(u_{i,j} + u_{j,i})$. The equilibrium equations include conservation of mass

$$\nabla \cdot u = 0, \quad (2)$$

momentum

$$\nabla \cdot \tau = -\Delta \rho(T, X, \phi) g \hat{z}, \quad (3)$$

and energy

$$\frac{\partial T}{\partial t} = \kappa \nabla^2 T - u \cdot \nabla T - \frac{T \Delta S}{c_p} \dot{M} \quad (4)$$

(see Table 1 for definition of variables). Eq. (2) satisfies the Boussinesq approximation and neglects dilational flow due to the extraction of melt which is likely to be small [19]. Eq. (3) balances viscous stresses with the body force due to density variations which depend on potential temperature $T$, melt depletion $X$, and mantle porosity $\phi$, according to,
\[ \Delta \rho = -\rho_o \left( \alpha T + \beta X + \frac{\rho_o - \rho_m}{\rho_o} \phi \right). \]  

Eq. (4) balances energy transfer associated with heat conduction, heat advection, and latent heat loss due to melting. Melt depletion is governed by

\[ \frac{\partial X}{\partial t} = -\mathbf{u} \cdot \nabla X + \dot{M} \]  

where \( \dot{M} \) is melt fraction and \( \dot{M} = \frac{\partial M(p, T)}{\partial t} \).

To estimate the distribution of porosity \( \phi \), we assume that melt migrates vertically through the mantle at a melt-mantle velocity contrast \((\omega - w)\) as governed by Darcy's flow law,

\[ \phi(\omega - w) = \frac{(\rho_o - \rho_m)gK}{\eta_m}. \]

Permeability \( K \) depends on grain size \( b \) according to \( K = \frac{b^2 \phi^2}{72 \pi} \). Finally, the rate of melt percolation is assumed to be equivalent to the rate at which melt is generated such that

\[ \phi(z) \omega(z) = \frac{\rho_o}{\rho_m} \int \dot{M} dz. \]

3. Numerical method and boundary conditions

To solve the above equations, we use a Cartesian numerical code presented by Gable [20, 21]. Time integration is achieved by iterating through discrete time steps, during each of which we solve for mantle flow, mantle potential temperature, and melt depletion. In solving the dimensionless forms of the flow equations (Eqs. 1-4), horizontal derivatives are expressed in terms of their Fourier components while vertical derivatives are expressed as finite difference approximations. We then invert for horizontal and vertical components of velocities and stresses using a standard relaxation method.

The dimensionless form of Eq. (3) is
\[ \nabla \cdot \tau = \frac{\rho_o g D^3}{\kappa \eta_o} \left( \alpha T_o T + \beta X + \frac{\rho_o - \rho_m}{\rho_o} \phi \right), \]  

(9)

where primes denote dimensionless variables. The body force (right hand side of Eq. (9)) is the sum of three terms: the first term, which scales with \( T \), is a Rayleigh number, \( Ra = \frac{\rho_o g D^3}{\kappa \eta_o} \alpha T_o \); the second term, which scales with \( X \), is a melt depletion Rayleigh number, \( Ra_x = \frac{\rho_o g D^3}{\kappa \eta_o} \beta \); and the third term, which scales with \( \phi \), is a melt retention Rayleigh number, \( Ra_\phi = \frac{\rho_o g D^3}{\kappa \eta_o} \left( \frac{\rho_o - \rho_m}{\rho_o} \right) \). Assumed values for \( \beta \) and \( \left( \frac{\rho_o - \rho_m}{\rho_o} \right)\) are 0.06 [12, 16] and 0.121 [14, 18], respectively. Consequently, depleting the mantle by 25% yields a density reduction equivalent to heating the mantle by 440°C, while a melt porosity of 3% yields a density reduction equivalent to heating the mantle by 107°C.

We assume that mantle viscosity varies with real temperature \( T_R \) and pressure according to

\[ \eta = \eta_o \exp \left\{ \frac{E + pV}{RT_R} - \frac{E + \rho_o g (0.5D)V}{RT_o} \right\}, \]  

(10)

where reference viscosity \( \eta_o \) is defined as the mantle viscosity for \( T=T_o \) and \( z=0.5D \); \( T_R \) in Kelvin is \( (T + 0.6z + 273) \), where the term 0.6z takes into account the adiabatic gradient; and \( T_o \) is the real temperature value of \( T_o \). To approximate numerically the effects of non-Newtonian rheology, we use reduced values of activation energy \( E \) and activation volume \( V \) [22] (Table 1). Because lateral variations in viscosity introduce nonlinearity to the above flow equations, we linearized the equations by introducing additional body force terms [20, 23]. The nonlinear terms and solutions were then updated upon successive iterations until solutions converged to our specified limit. We found that a convergence criterion of 0.1-0.5% yielded time-integrated solutions with errors of <0.5% while minimizing computing time. This computational method was tested in 2D with independent finite element solutions, while in 3D, it produced solutions within 2.6% of the best-estimated extrapolated solutions of a benchmark problem of ref. [24].
The final velocity field is then used in the advection term in Eq. (4) to solve for a new temperature field. Our energy solver uses finite differences with a tensor diffusion scheme to reduce numerical diffusion which is intrinsic to finite difference methods [20, 21]. The same tensor diffusion method is used to solve Eq. (6) for the depletion field. Vertical flow determines the rate of decompression melting, comprising the source terms in Eqs. (4) and (6). The melting-rate term in Eq. (4) is latent heat loss, which inhibits buoyant mantle flow by increasing both mantle density and viscosity, while the melting-rate term in Eq. (6) generates low-density depleted mantle residuum. To calculate melting rate $\dot{M}$, we incorporate the solidus and liquidus functions of McKenzie and Bickle [25] , as well as their functional dependence of $M$ on homologous temperature for adiabatic batch melting.

The rate of melting also determines the volume fraction of melt retained in the mantle $\phi$, which is the source of retention buoyancy. To compute porosity we combine Eqs. (7) and (8) and solve the integral in Eq. (8) numerically similar to ref. [18]. The grain-size-dependent melt permeability that we incorporate results in maximum porosities of 1-3% which is slightly higher than the 0.1-1% porosity range inferred from $^{238}\text{U}-^{230}\text{Th}-^{226}\text{Ra}$ disequilibria in Hawaiian lavas [26].

The numerical model setup is illustrated in Fig. 2. A ridge axis ($x=0$) is simulated by defining reflecting temperature (i.e., zero heat flux) and flow (i.e., zero shear stress) boundary conditions at the vertical sides, and setting the top boundary ($z=0$) to move at a constant half-spread rate $0.5U$. Temperature at the surface ($z=0$) is maintained at 0°C which cools and thickens a high-viscosity lithosphere approximately with the square root of $x$. A plume is introduced by imposing a columnar-shaped temperature anomaly in the lower portion of the box, centered beneath the ridge axis. The plume is hottest ($T=T_o+\Delta T_p$) at its center and cools as a Gaussian function of radial distance to $T_o$ at its radius $a$. We exploit the symmetry in $x$ and $y$ by centering the plume column at $x=y=0$, which allows a quarter plume in solution space to represent a fully circular plume in virtual space. In the lower portion of the box ($z > 0.6D$), we impose the potential temperature to be $T_o$ everywhere except inside the plume source. Thus, the energy equation is solved only in the upper portion of the box ($0.6D \leq z \leq 0$).

To ensure numerical accuracy in the flow solutions, we set a non-dimensional viscosity ($\eta/\eta_o$) upper limit of 200 and set a lower limit of 0.1. The upper viscosity limit is sufficient to accurately simulate a rigid lithosphere (i.e., $u=U$ and $v=w=0$ in the lithosphere), while the lower limit allows us to incorporate the full viscosity reduction in a plume with temperature anomaly of 200°C. The depth dependence of viscosity yields a
factor of ~4 viscosity increase between top and bottom of the box for a constant mantle temperature.

4. Steady-state along-axis width of a mantle plume head

We seek here to quantify the effects of melting on mantle flow and thus the dependence of along-axis plume width $W$ on plume flux $Q$ and plate spreading rate $U$. We began numerical experiments with the steady-state temperature solution of a ridge without the plume. Then after activating the plume, we integrated through time until both along-axis plume width and plume flux converged to steady-state values. We ran four sets of experiments: experimental set A (Table 2a) includes only thermal buoyancy and omits all melting effects; set B (Table 2b) considers only thermal buoyancy but includes latent heat loss; set C (Table 2c) includes additional buoyancy from melt depletion; and set D (Table 2d) includes additional buoyancy from melt retention.

Fig. 2 shows an example steady-state velocity and temperature field for a calculation in set A with a plume source temperature anomaly of 200°C (model 5a). Velocity vectors illustrate the plume rising from the conduit source and then spreading both perpendicular to and along the ridge axis after it impinges on the base of the lithosphere. Combined effects of thermal buoyancy and reduced plume viscosity result in a maximum plume upwelling rate of 244 km/my, which is >20 times that of the half spreading rate of 10 km/my. The corresponding average upwelling rate in the melting zone ($z \leq 110$ km) is 85 km/my.

Fig. 3a shows the steady-state velocity and mantle density fields for the same plume source temperature anomaly but with the additional effects of latent heat loss (model 5b). In the melting region of the plume center, potential temperatures are ~130°C cooler and consequently the plume is 65% less buoyant and 3 times more viscous than the calculation without latent heat loss (Fig. 2). The resulting average upwelling rate in the melting zone is 50 km/my, only ~60% of the predicted average upwelling rate of the model without latent heat loss (model 5a).

The addition of melt depletion buoyancy in model 5c generates an additional ~1% lateral density contrast between the plume center and the mantle beneath normal ridge sections far from the plume (Fig. 3b). The resulting average melting-zone upwelling rate is 67 km/my. As material rises more rapidly in the plume center, it spreads more rapidly along the base of the rigid lithosphere. This in turn inhibits upwelling at radial distances of 100-150 km shown as negative velocity differences in Fig 3b.
Finally, model 5d considers the additional buoyancy from melt retention (Fig. 3c). The high melting rate in the plume center results in a maximum porosity of 2.5%, to reduce bulk density in the plume center by an additional 0.3%. This added retention buoyancy further enhances the average upwelling rate in the melting zone to 77 km/my, which is ~90% of that predicted by the model that neglects all melting effects (model 5a). Thus, the added melting-related buoyancy forces approximately balance the upwelling-inhibiting effects of latent heat loss.

In all models examined we find, as did Ribe et al. [11], that the thickening lithosphere does not channel the plume preferentially along the ridge axis. On the contrary, the spreading lithosphere enhances ridge-perpendicular flow by pulling plume material away from the ridge-axis, and actually impedes along-axis flow by viscous shear. These effects however are small—the total along-axis flux at \(y=70\) km is within a few percent of the total ridge-perpendicular flux at \(x=70\) km. Thus, the rate of spreading away from the plume center is approximately equal in all radial directions.

To determine how \(W\) depends on \(Q\) and \(U\) for each experimental set, we examine spreading rates between 20 and 120 km/my and we vary \(Q\) by changing \(\Delta T_p\) between 100°C and 200°C (Table 2). We track the distribution of plume material by introducing a tracer \(P\) in the plume and using our tensor diffusion scheme to advect \(P\) passively with the mantle. \(P=1\) is introduced in the plume source column to represent 100% plume material, while \(P=0\) represents 0% plume material and 100% ambient mantle. We define \(W\) as the along-axis extent to which the depth-integrated tracer concentration

\[
\frac{1}{0.6D} \int_0^{0.6D} P(0,y,z)\,dz
\]

is \(>0.05\) (Fig. 2). The volume flux of the plume is measured at \(z=0.6D\) by integrating the vertical flow of the plume source over its cross-sectional area.

For calculations that include thermal buoyancy only without latent heat loss (set A), we find, similar to ref. [9, 11], that \(W\) depends primarily on the scaling quantity \((Q/U)^{1/2}\), and depends secondarily on the plume buoyancy number,

\[
B = \frac{Q \rho_o \alpha \Delta T_p}{48 \eta_p U^2}
\]

as defined in ref. [11], and on the ambient/plume viscosity ratio \(\gamma=\eta_0/\eta_p\), at \(z=0.5D\). A modified buoyancy number which depends on plume viscosity is thus \((B\gamma)\). The best fit linear regression function obtained by fitting linear and constant coefficients to \(\ln(B\gamma)\) is
5. Models of Iceland and the Mid-Atlantic Ridge

We next investigate models of mantle flow and melting beneath Iceland, a relatively well studied example of a ridge-centered plume. Our objective is to constrain the temperature

$$W = 2.35 \left( \frac{Q}{U} \right)^{1/2} (B\gamma)^{0.04}. \quad (11)$$

Calculated values of $W(Q/U)^{-1/2}$ range from 2.2 to 2.9 (Table 2) with a mean value of 2.50. To compare our results directly with those of Ribe et al. [11], we omit the dependence on $\gamma$ and incorporate their definition of $Q$ which is the integrated vertical plume flux weighted by plume temperature anomaly. With these modifications we obtain a best-fit linear regression of $W=2.80(Q/U)^{1/2}B^{0.05}$ which is in good agreement with that of Ribe et al. [11] of $W=2.93(Q/U)^{1/2}B^{0.052}$. While the scaling and exponential factors vary slightly between our results and those of ref. [9] and [11], the general form of Eq. (11) is robust and insensitive to differences in far-field experimental boundary conditions.

For calculations of thermal buoyancy with latent heat loss (set B), we obtain a best-fit linear regression function,

$$W = 2.21 \left( \frac{Q}{U} \right)^{1/2} (B\gamma)^{0.02}. \quad (12)$$

The smaller constant and exponential coefficients relative to those in Eq. (11) reflect the inhibiting effects of latent heat on along-axis plume spreading. The average values of $W(Q/U)^{-1/2}$ for experimental set B is 2.29, or $\sim 92\%$ of the average in set A.

Addition of depletion buoyancy in experimental set C results in a best-fit regression function,

$$W = 2.37 \left( \frac{Q}{U} \right)^{1/2} (B\gamma)^{0.04}. \quad (13)$$

This function is essentially the same as that of Eq. (11) for set A. The average value of $W(Q/U)^{-1/2}$ of 2.51 is also essentially the same as that in set A. The further addition of melt retention (set D) does not change this relationship significantly as shown by the similarity in regression lines of set C and set D (Fig. 4). Thus, the effects of retention buoyancy occurs at wavelengths too short to affect the full width $W$. In summary, the effects of latent heat loss to inhibit lateral plume spreading are approximately balanced by the added buoyancy of melt depletion which enhances plume spreading.
anomaly, dimension, and volume flux of the Iceland plume by comparing theoretical model predictions with observed along-axis variations in seismic crustal thickness, topography, gravity, and basalt geochemistry. Previous geophysical studies of the Iceland-MAR system demonstrated that the topographic high at Iceland coincides with a low in mantle-Bouguer gravity anomaly (MBA), and that both MBA and topographic anomalies can be explained by the combined effects of anomalously thick crust and low density mantle generated by the Iceland plume [27, 28]. MBA are calculated by subtracting from free-air gravity the attraction of seafloor topography and the crust-mantle interface assuming a uniform crustal thickness of 7 km (e.g., [29, 30]). Because as much as 75% of the along-axis topographic and MBA variations may arise from thickened igneous crust [28, 31], crustal thickness calculations are an important link between our models and surface observations.

To predict crustal thickness from mantle melting calculations, we assume that all melt generated within 200 km of the ridge axis accretes perpendicularly to the ridge axis and take the top of our numerical box to be the isostatic depth of the seafloor for crust of normal thickness (7 km). The crustal thickness as a function of along-axis coordinate $y$ is therefore

$$Cr(y) = \frac{2}{U} \left( \frac{\rho_c}{\rho_m} \right) \int M(y) dx dz. \quad (14)$$

We take the top of our model to be the isostatic depth of the seafloor for a 7-km-thick model crust, and assume isostatic compensation of crustal thickness variations that deviate from this model crust. Consequently, variations in crustal thickness impart no lithostatic pressure variations in the mantle. To prevent melting at depths shallower than the isostatic base of the thickened Icelandic crust we prohibit melting everywhere at depths <28 km. Melting may stop deeper, however, if hydrothermal cooling is important [32].

To calculate isostatic topography of the seafloor, we consider contributions from both the crust ($\Delta h_c$) and mantle ($\Delta h_m$). In calculating $\Delta h_c$, we assume Airy compensation of the crust with a surface density contrast of $(\rho_c-\rho_w)$ for the submarine portion of topography and $\rho_c$ for the subaerial portion. The crust along the Reykjanes and Kolbeinsey Ridges is assumed to have a density of 2800 kg/m$^3$ except within 500 km of the plume center, where we increase it linearly to a maximum of 3030 kg/m$^3$ at Iceland, to account for the higher
MgO content of the Icelandic crust [33]. The mantle contribution to topography, or dynamic topography is calculated from vertical normal stress at the top layer of our model,

\[ \Delta h_m = \frac{\tau_{zz}}{(\rho_o - \rho_w)g} \]  

(15)

With this definition, our calculations predict seafloor depths to increase approximately with the square-root of distance from the ridge-axis which is consistent with lithospheric half space cooling models (e.g. [34]). In addition to using \( \Delta h_m \) to predict topography, we also use \( \Delta h_m \) to estimate crustal thickness in a manner independent of our mantle melting calculations. This "isostatic crustal thickness" is defined as the isostatic thickness of crust required to account for the difference between the observed topography and \( \Delta h_m \).

In computing MBA we again consider both crustal and mantle contributions. The crustal contribution is the gravitational signal due to undulations at the crust-mantle interface that deviate from the constant crustal thickness reference model originally assumed in generating MBA. For these calculations we employ the method of ref. [35]. The mantle contribution to gravity is calculated by integrating the contributions from lateral density variations at each model layer [29].

5.1 Broad plume source model

Our first model of the Iceland-MAR system, much like that of Ribe et al. [11], considers a broad plume source with a relatively small temperature anomaly (model Ice 1, \( a=300 \text{ km}, \Delta T_p=75^\circ \text{C} \)) rising beneath a model MAR with a full-spreading rate of 19 km/my [36] (Fig. 5a). At this spreading rate, \( T_0=1350^\circ \text{C} \) is required to produce a \( \sim 7 \text{ km-thick}, \) normal oceanic crust. The calculation that includes all melting effects (model Ice 1d) predicts a plume volume flux of \( \sim 1.2 \times 10^7 \text{ km}^3/\text{my}, \) generating an along-axis plume-head width \( W \) of \( \sim 2300 \text{ km} \) (Fig.5a). The predicted maximum upwelling rate in model Ice 1d is 105 km/my, which is >10 times that beneath the unaffected portion of the ridge far from the plume. The predicted upwelling rate averaged through the melting zone in plume center is 20 km/my. Melt retention buoyancy contributes minimal effects to this average upwelling rate and thus very little to melting rate.

The enhanced upwelling rate in the plume center, combined with an increase in total melt extent (23% compared to 13% beneath the ridge far away from the plume), generates a maximum crustal thickness of \( \sim 30 \text{ km} \), consistent with the seismic measurements on Iceland [37] (Fig. 5b). Along the length of the Reykjanes Ridge, the crustal thickness...
profiles predicted by melting in model Ice 1d shows striking similarity to the seismic measurements. From the plume center, the predicted crust first thins to 9.5 km at an along-axis distance of ~300 km, then thickens to 11 km at a distance of ~500 km, and finally tapers to a thickness of 6.7 km at a distance of ~1300 km. The predicted local minimum in crustal thickness at y~300 km is caused by a reduced mantle upwelling rate at the plume edge caused by the rapid vertical flux in the plume center. Melt retention does not significantly affect crustal thickness because the predicted 0.5% contrast in porosity between the plume center and normal sub-ridge mantle is too small to appreciably enhance plume upwelling rate in the shallowest 100 km, where melting occurs. The isostatic crustal thickness profile of model Ice 1d also shows good agreement with the observed crustal thickness profile (Fig. 5b). The excess magmatic flux rate required to sustain the anomalous (in excess of a 7-km-thick crust) isostatic crust along the MAR, 1000 km north and south of Iceland, is 2.33x10^5 km^3/my. This value is within a few percent of the 2.45x10^5 km^3/my excess crustal production rate predicted from our melting model.

The predicted topography from the melting-model crustal profile generates 70% (~2.5 km) of the total along-axis topographic anomaly of ~3.5 km (Fig. 5c). We predict the remaining 30% (~1 km) of topography to be supported by dynamic mantle uplift which is obtained with a β value of 0.024 [12, 17]. Of mantle dynamic topography Δh_m, thermal buoyancy generates ~70% while depletion and retention buoyancy generate the remaining 22 and 8%, respectively. The predicted total amplitude of Δh_m is consistent with the 0.5-1.5 km of Eocene uplift as inferred from sediment core analyses [38].

The mantle-Bouguer anomaly along the submarine portions of the ridge is also matched well by predictions of model Ice 1d using both the melting-model and isostatic crust (Fig. 5d). Similar to bathymetry, the crustal MBA accounts for most (70%) of the total predicted anomaly of ~330 mGal with the mantle contributing the remaining 30%. Of the predicted mantle gravity signal, 75% is from thermal expansion, while 20 and 5% are generated by melt depletion and retention, respectively. The successful predictions of both topography and MBA support the hypothesis that these anomalies are from the same sources: primarily crustal thickness variations and secondarily density variations in the shallow mantle.

5.2 Narrow plume source model

Our second set of models (Ice 2) represent another end-member possibility—that of a narrower and hotter plume source (Fig. 6a; a=60 km, and ΔT_p=170°C). With all melting effects included, model Ice 2d predicts a plume volume flux of 2.1x10^6 km^3/my which
spreads plume material to a full width \( W \) of 870 km along the ridge axis. The maximum upwelling rate of model Ice 2d is 283 km/\( \text{my} \), which is >2.5 times greater than the maximum upwelling rate in the broad plume source (model Ice 1d), and ~30 time faster than normal ridge upwelling rates. In addition, the maximum extent of melting is increased to 30%. Thus a larger volume of mantle material is predicted to circulate more rapidly through a thicker melting zone relative to that of Ice 1d, which results in melting rates an order of magnitude greater than those in model Ice 1d (Fig. 6a). For the model without melt retention (model Ice 2c), the melting-zone averaged upwelling rate is 63 km/\( \text{my} \) and the maximum melting-model crustal thickness is 147 km. With melt retention (model Ice 2d), the 2.9% porosity in the plume is sufficient to increase the predicted melting-zone-averaged upwelling rate to 80 km/\( \text{my} \) and the maximum melting-model crustal thickness to 166 km (Fig 6b). In model Ice 2d, the melting-model crust thins to 3 km at an along-axis distance of 120 km, where upwelling and thus melting rate is strongly reduced at the edge of the rapidly upwelling plume center (Fig. 6a).

The high maximum crustal thicknesses predicted by the narrow plume source, melting model drastically exceed calculations of previous studies that assumed passive mantle upwelling (e.g. ref. [28, 39]) and drastically exceed the observed crustal thicknesses (Fig 6b). The resulting topographic and MBA anomalies also fail to match the observations (Fig. 6c, d). The isostatic crustal profile, on the other hand, yields predictions in much better agreement with the observed crustal thicknesses (Fig 6b), topography (by definition) (Fig. 6c), and MBA (Fig. 6d) along the ridge axis. Thus, if the Iceland plume is comparable in radius and temperature to our narrow plume source model, a substantial portion of the melt produced beneath Iceland must accrete more uniformly along-axis than our melting-model crust, much like our isostatic crustal profile. This condition suggests melt migration and/or lower crustal ductile flow [40] occurs over distances of several hundreds of kilometers away from Iceland along the Reykjanes and Kolbeinsey Ridges.

Because the mechanisms of along ridge-axis melt transport are poorly understood, we do not attempt to model this process in this study. Instead, we assume a priori that along-axis melt redistribution does occur and that the end result of this process leads to the isostatic crustal profile. In arriving at our final Ice 2 models, we thus sought values of \( \Delta T_p \) and \( a \) such that the total volume rate of melt produced by the melting model matched that required to sustain the isostatic crustal profile. The best solutions of \( \Delta T_p=170^\circ \text{C} \) and \( a=60 \) km yield a total excess melt production rate of \( 2.54\times10^5 \text{ km}^3/\text{my} \) (model Ice 2d), which is within 1% of that required of the isostatic crustal profile.
In these narrower, hotter plume source models, the mantle contribution to topography and gravity relative to the crustal contribution becomes much larger than in the broader, cooler source models. For example, model Ice 2d predicts a mantle topographic uplift that is 51% (1.8 km) of the observed along-axis topographic anomaly (Fig. 6c), and a mantle contribution to MBA that is 48% (158 mGal) of the observed MBA variation (Fig. 6d). The crust therefore generates only 49 and 52% of the total topographic and MBA variations, respectively. Calculations also predict the importance of melt-related buoyancy to the mantle anomalies to be significantly greater for these hotter plume source models relative to the cooler source models. Thermal buoyancy is predicted to produce 47% of $\Delta h_m$, and 60% of the mantle MBA variation; melt depletion produces 39% of $\Delta h_m$ and 25% of the mantle MBA; and melt retention produces the remaining 14% of $\Delta h_m$ and 15% of the mantle MBA variation.

5.3 Reykjanes Ridge bathymetric swell

Similar to along-axis topography, we predict map view topography by adding mantle dynamic topography (Eq. (15)) and isostatic topography of the crust considering only along-axis variations in crustal thickness. For model Ice 1d, we use the melting-model crust and for model Ice 2d, we use the isostatic crust. Fig. 7 illustrates the observed topography in map view along the Reykjanes Ridge south of Iceland, and predictions of models Ice 1d and Ice 2d. The similarity between the predictions and observations at broad wavelengths (>~500 km) are compelling: both models predict the ~2.0 km across-axis decrease in broad wavelength topography between Iceland and an across-axis distance of 400 km away from the ridge-axis, and both predict the south-pointing swell, elongated along the Reykjanes Ridge. As demonstrated above, the southward deepening of the ridge axis reflects crustal thinning and mantle density increase with distance from the Iceland plume source. But perpendicular to the ridge-axis, seafloor topography is dominated by the subsidence of the cooling lithosphere. Thus, contrary to previous notions (e.g. [5, 6]), the regional bathymetric swell does not require a pipe-like flow of plume material along the ridge axis. Instead, we predict the plume head to spread radially and explain the general shape of the elongated Icelandic swell as the superposition of radial plume spreading and across-axis lithospheric cooling. The models presented in this study, however, do not consider time-dependent variations in crustal accretion which may also contribute to across-axis topographic variations.
5.4 Rare-earth element and isotopic anomalies

A potentially useful independent constraint on melting depth and extents, which reflect mantle temperature, is rare-earth element (REE) concentrations of axial basalts. A simple comparison can be made with previous inversions of melt fraction versus depth as calculated by White et al. [33]. At the plume center, our broad plume source model (Ice 1d) and narrow plume source model (Ice 2d) predict melt fractions that are lower and higher, respectively, than White et al.’s [33] inversions for Krafla volcano on Iceland (Fig. 8a). The potential temperature of the Iceland plume-source, therefore, is likely to be 1425-1520°C as represented by our two end-member models. At ~550 km from Iceland on the Reykjanes Ridge, model Ice 1d predicts melting depths and extents closely matching those obtained from the REE inversions [33] (Fig. 8b). Model Ice 2d, however, underpredicts the extents and depths because plume material from our narrow plume source did not spread to this along-axis distance. Thus, in order to explain the REE composition of basalts sampled 550 km away from Iceland, once again our model Ice 2d seems to require plume-derived melts to migrate substantially along the Reykjanes Ridge axis.

While REE concentrations reflect melting process beneath Iceland, Sr isotope ratios may reflect the concentration of the plume source material relative to that of normal mid-ocean ridge basalts (MORB). Schilling [8, 41] interprets the peak in $^{87}$Sr/$^{86}$Sr at Iceland to mark the center of the Iceland plume, where the plume source concentration is highest, and interprets the decrease in $^{87}$Sr/$^{86}$Sr north and south of Iceland to reflect a decrease in percent of plume material comprising the mantle melt source.

To address questions of where and how plume-MORB mixing occurs, we calculate the fraction of plume tracer $P$ in accumulated melts along the model ridge axis (neglecting along-axis melt migration) (Fig 8c). At each numerical grid where new melt is generated, $P$ is weighted by melting rate. We then integrated over each ridge-perpendicular plane to compute a weighted mean value ( $\bar{P}$ ) for each point along the ridge axis,

$$\bar{P}(y) = \frac{\int P(x,y,z)M(x,y,z)dxdz}{\int M(x,y,z)dxdz}$$ (16)

This calculation thus approximates the plume concentration of pooled melts along the ridge axis. For example, $\bar{P}=1.0$ indicates that all of the melt generated in a plane perpendicular to that point of the ridge is entirely plume-source derived. Likewise, $\bar{P}=0.0$ indicates that none of the melts are plume derived and $0.0 < \bar{P} < 1.0$ indicates plume-MORB mixing.
Model Ice 1d predicts an along-axis geochemical plume width of >2000 km, significantly greater than that suggested by the $^{87}\text{Sr}/^{86}\text{Sr}$ anomaly. Ice 2d on the other hand predicts a width of ~1000 km which is more consistent with that of the $^{87}\text{Sr}/^{86}\text{Sr}$ anomaly; however, its profile in $\bar{P}$ would likely be broader if along-axis melt migration were considered. Both model Ice 1d and Ice 2d predict that the melts are entirely plume derived ($\bar{P}=1.0$) over most of the plume width, and become fully ambient mantle derived ($\bar{P}=0.0$) within 200-300 km of the edge of the plume. These results suggest that within most of the plume affected portion of the ridge, very little mixing occurs between plume and ambient source material in the shallow mantle. Thus, if the gradients in $^{87}\text{Sr}/^{86}\text{Sr}$ away from Iceland reflect plume-MORB mixing, it most likely occurs deeper in the mantle, possibly by ambient mantle entrainment of the ascending plume (e.g. [42]).

5.5 Predictions of P-wave seismic velocity anomalies

Observations of compressional wave (P-wave) seismic travel time variations and associated mantle P-wave velocity variations provide critical constraints on mantle properties beneath Iceland. To predict P-wave seismic velocity anomalies, we assume a reference P-wave velocity of 8 km/s, which decreases by $6.25\times10^{-3}\%$ for each 1°C increase in mantle temperature, increases by 0.1% for each 1% increase in depletion, and decreases by 1.25% for each 1% increase in pore volume [43]. We also predict P-wave travel-time residuals by calculating travel times of seismic rays passing vertically through the 400 km thickness of our mantle models.

The broad plume source model (Ice 1d) predicts a maximum decrease in P-wave velocity below the melting region of ~0.5% relative to the surrounding mantle. In the melting region, the predicted P-wave velocity anomaly diminishes because the velocity-enhancing effects of latent heat loss and melt depletion exceed the velocity-reducing effect of melt retention (Fig. 9a). The corresponding travel-time delay for vertically passing rays is predicted to be +0.23 s at the plume center and decrease to zero at an along-axis distance of ~1200 km. The contributions to travel-time delay above the plume center are +0.25 s from excess mantle temperature, -0.09 s from melt depletion, and +0.07 s from melt retention. Across the ridge-axis, lithospheric cooling dominates, resulting in a predicted travel-time difference of 0.5 s between the plume center and at an across-axis distance of 400 km. The broad plume source model thus predicts only a gradual decrease in travel-time delay across the ridge axis and even smaller variations along the ridge axis.
In contrast, the narrow plume source of model Ice 2d predicts significantly larger amplitudes of P-wave anomalies over a much narrower lateral extent. Below the melting zone, the 170°C plume temperature anomaly reduces calculated P-wave velocities by more than 1%. In the melt zone, however, the P-wave velocities are reduced to as much as 2% due to the 2.9% melt retention (Fig. 9b). Along the ridge axis, the travel-time delay for vertically passing rays is predicted to be +0.75 s at the plume center and to decrease by 0.85 s within ~80 km. Approximately half of this travel-time residual is predicted to arise in the high-porosity melt zone in the shallow mantle. Across the ridge axis, the additional effect of lithospheric cooling yields a predicted travel-time difference of 1 s within ~80 km of the plume center and a travel-time difference of 1.2 s over an across-axis distance of 400 km. Preliminary results of the ongoing ICEMELT experiment at Iceland have revealed azimuthal variations in P-wave travel times as high as 1 s within 100 km of the ridge axis [44], suggesting that the narrow plume source model better represents Iceland than does the broad plume source model.

6. Discussion

6.1 Importance of melting effects

The importance of melting effects on mantle flow, melt production, and surface observables are summarized in Fig. 10. Mantle melting generates appreciable effects on mantle properties; however, over the range of plume viscosities considered in our models, the effect of latent heat loss on mantle flow largely cancels the effects of depletion and retention buoyancy. As a result, the combined effects of these factors on mantle flow are small as reflected in the small changes in the predicted values of $W(Q/U)^{-1/2}$ (Figs. 4 and 10). Similarly, when plume temperature anomalies are mild as in the Ice 1 models, the melting-related factors have only second order effects on upwelling rate as reflected in small changes in the predicted crustal thickness (Fig. 10). When plume temperature anomalies are larger, however, as in the Ice 2 models, melt retention may enhance the predicted crustal thickness by 20% relative to calculations that do not include retention.

Contrasting with their mild influence on mantle flow, the melting-related factors have substantial effects on the predicted geophysical observables and these effects increase with increasing plume temperature (Fig. 10). For mantle contributions to topography and MBA, latent heat loss reduces the amplitudes of predicted anomalies by 20-40% relative to calculations without latent heat loss. Depletion buoyancy increases predicted mantle topographic anomalies and MBA by 10-65% relative to calculations without depletion,
while retention buoyancy increases predicted anomalies by 5-25% relative to calculations without retention. Melting effects on P-wave delay-time are also important: Latent heat loss decreases predicted delay-time by \(-13\%\), melt depletion decreases delay-time by 20-30\%, but melt retention increases delay-time by 20-60\%. It is thus important to consider melting effects on mantle properties when predicting geophysical observables.

6.2 Model uncertainties

Because melting-related factors do not affect significantly large-scale mantle flow, uncertainties associated with our melt calculations such as the assumed batch melting [25], our choice of \(\beta\) values, and the melt porosity calculations, are likely to have only secondary effect on our estimates of plume source radius and temperature. By far the most important uncertainty in this regard is mantle rheology. The reference mantle viscosity \(\eta_0\) controls directly the rate of mantle upwelling in response to density variations (Eq. (9)). But unfortunately, viscosity beneath ridges is not known to within one or even two orders of magnitude (e.g. [45]). One mechanism that may yield a substantially higher viscosity than that we have assumed is dehydration at the onset of melting [45]. A higher melting zone viscosity, for example, would most likely require a greater temperature anomaly of the broad plume source model to explain the geophysical observations, or require a greater source radius and less along-axis melt redistribution of our narrow plume source model to explain the observations. Thus, because of the uncertainty of viscosity, our Iceland plume models are not unique. However, they do provide reasonable bounds on the plume source radius and temperature given the similarities between model predictions and the variety of geophysical and geochemical observations considered.

6.3 Plume volume flux estimates

Still, it may be possible to constraint plume volume flux independent of ambient viscosity based on the observed MBA and bathymetric anomaly widths and the theoretical relationship between flux and \(W\) (i.e. Eq. (13)). The use of Eq. (13) to infer plume volume flux is valid if the surface anomaly widths reflects directly the along-axis plume width in the mantle, which would be the case if along-axis melt migration is negligible as assumed in the Ice 1 models. The flux required to match the along-axis MBA and bathymetric anomaly widths as predicted from model Ice 1d is \(1.2 \times 10^7\) km\(^3\)/my. This flux, however, is several times larger than previous estimates of the Iceland plume of \(2 \times 10^6\) km\(^3\)/my [46], \(1.43 \times 10^6\) km\(^3\)/my [8], and \(2.2 \times 10^6\) km\(^3\)/my [28]. If on the other hand,
along-axis melt migration is important as suggested for the Ice 2 models, we can not use Eq. (13) to constrain the Iceland plume volume flux independent of $\eta_0$. We must therefore rely on the fact that our melt production rate estimates are consistent with the total volume of observed excess crust as we did for the Ice 2 models. Indeed, model Ice 2d predicts a plume volume flux of $2.1 \times 10^6$ km$^3$/my which is more consistent with the above estimates of the previous studies. An intriguing new question arising from this narrow plume source model is, what specific mechanisms may allow melt generated beneath Iceland to migrate hundreds of kilometers along-axis? Possible evidence for such melt transport may include the V-shaped axial bathymetric highs propagating away from Iceland along the Reykjanes Ridge as first noted by Vogt [47] in 1971.

7. Conclusions

We have investigated the dynamics of mantle flow and melting of a ridge-centered plume using three-dimensional, variable-viscosity models with focus on three buoyancy sources: temperature, melt depletion, and melt retention. When all melting effects are considered, the relationship between along-axis plume width $W$, plume volume flux $Q$, full spreading rate $U$, buoyancy number $B$, and ambient/plume viscosity ratio $\gamma$, is best parameterized by $W=2.37(Q/U)^{1/2}(B\gamma)^{0.04}$. Calculations that include melting yield a similar relationship to those that do not include melting because of the competing effects of latent heat loss and depletion buoyancy. We propose two end-member models for the Iceland plume beneath the MAR. The broad plume source of radius=300 km represents a low temperature ($\Delta T_p=75^\circ$C) and high flux ($Q=1.2 \times 10^7$ km$^3$/my) end-member, while the narrow plume source of radius=60 km represents a high temperature ($\Delta T_p=170^\circ$C) and low flux ($Q=2.1 \times 10^6$ km$^3$/my) end-member. The broad plume source predicts successfully the observed along-axis variations in seismic crustal thickness, topography, and mantle-Bouguer gravity anomalies; whereas the narrow source model predicts adequately the total excess crustal production rate ($2.5 \times 10^5$ km$^3$/my) but requires extensive melt migration and/or lower crustal ductile flow to occur over hundreds of kilometers along the MAR in order to explain the geophysical and geochemical observations. Our calculations predict that plume spreading away from the plume center is radially symmetric rather than channeled preferentially along the ridge axis. The elongated bathymetric swell along the Reykjanes Ridge can be explained by rapid off-axis subsidence due to lithospheric cooling superimposed on a broader hotspot swell. Both the broad and narrow plume source models predict very little mixing between the plume and MORB sources in
the shallow mantle; hence, we suggest that mixing may occur deeper in the mantle possibly due to entrainment of the isotopically depleted portion of the mantle by the rising mantle plume. Our narrow plume source model predicts seismic P-wave velocity variations more consistent with recent seismic observations beneath Iceland, suggesting that this model may better represent the Iceland plume.

Acknowledgments

We gratefully acknowledge N. Ribe, D. Sparks, and C. Wolfe for their constructive and timely reviews. We thank Y. Shen and P. van Keken for supplying independent finite element solutions used to test our variable viscosity flow solver. This paper also benefited from discussions with R. Detrick, J. G. Schilling, and M. Spiegelman. This work was supported by NSF grant OCE-9302915 and benefited from collaborations facilitated through a NSF-supported Mantle Convection Workshop at the Los Alamos National Laboratories and additional funds granted through the WHOI Education Office. Contribution 9217 of the Woods Hole Oceanographic Institution.

Fig. 1. Combined shipboard and Etopo5 bathymetry map (contour interval of 0.5 km) showing Iceland (65°N, 18°W) and the Reykjanes (south of Iceland) and Kolbeinsey (north of Iceland) Ridges. Bold lines marks the ridge axes. This figure and Figs. 4, 7, 8, and 10 were produced using the GMT software package [48].
Figure 1
Fig. 2. Perspective diagram illustrating steady-state flow (small arrows) and potential temperature (shaded and contoured at 100°C-intervals) fields of an example calculation that considers thermal buoyancy only and no melting effects (model 5a). Vertical plane on the right is a depth cross-section along the ridge axis (x=0), while the vertical plane to the left is a depth cross-section perpendicular to the ridge axis (y=0). Top plot shows depth-averaged plume tracer concentration $P$ along the ridge axis which we used to define plume width $W$. Both top ($z=0$) and bottom ($z=D$) boundaries are isothermal planes with the bottom, a free slip boundary and the top, fixed at a horizontal velocity of $0.5U$ (large horizontal arrow). All boundaries are closed to flow both in and out of the numerical box, thus material flows downward at the end of the box opposite the ridge (x=800 km) and recirculates toward the ridge axis along the base of the box. The effect of this recirculation on the interaction between plume and ridge are insignificant.
Figure 2
Fig. 3. Perspective views of depth cross-sections showing % density reduction in the mantle due to (a) thermal buoyancy with latent heat loss ($\Delta T_p=200^\circ C$) (model 5b), (b) plus melt depletion buoyancy (model 5c), and (c) plus melt retention buoyancy (model 5d). Contour interval is 0.5%. Vectors in (a) show mantle flow. Vectors in (b) show the differences between flows with and without melt depletion buoyancy. Vectors in (c) show the difference between flows with and without melt retention buoyancy. Downward pointing vectors in (b) and (c) illustrate reduced upwelling, not downwelling.
Fig. 4. Numerical results (dots) of calculations with all melting effects included (set D). The two Iceland models are circled. The solid black line is the best-fit linear regression shown by Eq. (13) which yields a standard deviation misfit that is 7% of the median value of $W(Q/U)^{-1/2}$. Also shown are corresponding linear regressions of calculations of thermal buoyancy without latent heat loss (set A, gray), thermal buoyancy with latent heat loss (set B, dotted), and additional buoyancy from melt depletion (set C, dashed).
Figure 4
Fig. 5. (a) Perspective diagram of model Ice 1d (broad plume source) shaded according to temperature. Black contours are depletion (contour interval is 5%) and white contours are melting rates of 0.01, 0.03, and 0.05 my$^{-1}$. (b) Comparison between model Ice 1d melting-model crust (solid) and isostatic crust (dashed), and seismic crustal thickness measurements along the Reykjanes Ridge (dots) and at older seafloor near the continental margins (triangles) from ref. [37]. (c and d) Comparison between the observed bathymetry (thick gray curve in c) and MBA (thick gray curve in d) along the MAR and predicted profiles of model Ice 1d using the melting-model crust (bold curves in c and d) and isostatic crust (thick dashed curved in d). Also shown are predicted mantle components due to various mantle density sources as labeled. Bathymetry data and MBA are from ref [28]. We do not consider on-land gravity of Iceland.
Figure 5
Fig. 6. Same as Fig. 5 but for Ice 2 models (narrow plume source). Symbols are the same as in Fig. 5 except melting rate contours in (a) are 0.01, 0.03, 0.05, 0.2, 0.4 my⁻¹.

Fig. 7. (a) Observed topography of Iceland and the Reykjanes Ridge (oblique Mercator projection). (b) Mantle + crustal topography predicted from our broad plume source model Ice 1d using the melting-model crust. (c) Mantle + crustal topography predicted from our narrow plume source model Ice 2d using the isostatic crust.
Figure 7
Fig. 8. (a and b) Comparison between White et al.’s [33] REE inversion of melt fraction (gray) and our predictions from models Ice 1d (solid) and Ice 2d (dashed) at Krafla, near the plume center (a), and at DSDP Site 409 on the Reykjanes Ridge 550 km away from the plume center (b). This inversion method assumes fractional melting and includes differences in partitioning coefficients between the spinel and garnet stability fields. It also assumes complete extraction and mixing of all melts generated in the melting region, which makes the estimation of maximum depth of melting sensitive to the low-degree melt compositions [49]. Another assumption is the parent source composition (primitive mantle beneath Krafla and a 50-50% mix of primitive and depleted MORB source along the Reykjanes Ridge), which is important in estimating the maximum extent of melting. (c) Comparison between observed Sr isotope concentrations [41] along Iceland and the MAR and weighted mean plume tracer concentration $\bar{P}$ in the accumulated melts for models Ice 1d (solid) and Ice 2d (dashed). The peak in $^{87}$Sr/$^{86}$Sr to the north of Iceland is due to the Jan Mayen hotspot [41] which we do not model.
Figure 8
Fig. 9. (a) Lower diagram shows predicted P-wave velocity variations with contour interval of 0.5% for model Ice 1d (broad plume source) caused by the combined effects of temperature, melt depletion, and melt retention. Top panel illustrates the predicted P-wave travel-time delays, assuming vertically passing rays, for along axial and across-axis profiles due to successively added mantle effects as labeled. (b) Same as (a) but for model Ice 2d (narrow plume source). The lowest velocity region occurs at depths 50-100 km due to the predicted high melt retention.
Figure 9
Fig. 10. Characteristic variables predicted by models with melting normalized by those predicted by models without melting. We choose the mean value of $W(Q/U)^{-1/2}$ for each experimental set and maximum value of along-axis variations for each of the other variables. Crustal thickness anomalies are normalized by calculations with thermal buoyancy and latent heat loss.
Figure 10

The figure illustrates the percentage change in various geophysical parameters due to melting compared to non-melting conditions. The bars represent different calculations (Ice1 and Ice2) and show the impact of thermal and latent heat loss on these parameters.

- **W(Q/U)^{-1/2}**: Shows a significant decrease in the ratio of work to elastic strain energy.
- **Crustal Thickness Anomaly**: Displays a notable change in crustal thickness with ice accumulation.
- **Dynamic Topo.**: Reflects dynamic topography changes due to ice loading.
- **Mantle Gravity**: Indicates gravity anomalies related to mantle dynamics under ice loads.
- **P-Wave Delay-Time**: Reveals time delays in P-waves due to ice and mantle interactions.

The diagram includes two sets of calculations, labeled Ice1 and Ice2, with different shading to distinguish between them. The percentages are indicated along the x-axis, from 60 to 200%.
CHAPTER 4

**DYNAMIC INTERACTION BETWEEN MANTLE PLUMES AND MIGRATING MIDOCEAN RIDGES**
Dynamic interaction between mantle plumes and migrating midocean ridges

Abstract. We investigate the three-dimensional interaction of mantle plumes and migrating midocean ridges with variable viscosity numerical models. Scaling laws derived for stationary ridges in steady state with near-ridge plumes are consistent with those obtained from independent studies of Ribe [1996]. Our numerical results suggest that along axis plume width $W$ and maximum distance of plume-ridge interaction $x_{\text{max}}$ scale with $(Q/U)^{1/2}$, where $Q$ is plume source volume flux and $U$ is ridge full spreading rate. Both $W$ and $x_{\text{max}}$ increase with buoyancy number $\Pi_b$, which reflects the strength of gravitational- versus plate-driven spreading, and $\gamma$, which is the ratio of ambient/plume viscosity. In the case of a migrating ridge, the distance of plume-ridge interaction is reduced when a ridge migrates toward the plume due to the excess drag of the faster-moving leading plate, and enhanced when a ridge migrates away from the plume due to the reduced drag of the slower-moving trailing plate. Thermal erosion of the lithospheric boundary layer by the plume further enhances $W$ and $x_{\text{max}}$ but to a degree that is secondary to the differential migration rates of the leading and trailing plates. These numerical models are tested by comparing model predictions of bathymetry and gravity with observations of the Galápagos plume-migrating ridge system. The amplitudes and widths of along-isochron bathymetric and gravity anomalies can be explained with models of a plume source temperature anomaly of 80-120°C, radius of 80-100 km, and volume flux of $4.5 \times 10^6$ km$^3$/m.y. The observed increase in anomaly amplitude with isochron age is also explained by our models which predict higher crustal production rates when the ridge was closer to the plume source several million years ago. The same plume-source models also predict crustal production rates of the Galápagos Islands that are consistent with those estimated independently from the observed island topography. Predictions of the
geochemical signature of the plume along the present-day ridge suggest that mixing between the plume and ambient mantle sources, as inferred from geochemical observations, is unlikely to occur in the asthenosphere or crust. Instead, mixing most likely occurs much deeper in the mantle, possibly by entrainment of ambient material as the plume ascends through the depleted portion of the mantle from its deep source reservoir.

INTRODUCTION

A wide range of geologic and geochemical observations provide strong evidence that mantle plumes feed material to nearby midocean ridges [e.g. Vogt, 1971; Schilling, 1973; Schilling et al., 1976; Morgan, 1978]. Near-ridge plumes are documented to generate along-axis geophysical anomalies with widths exceeding 2000 km [Ito and Lin, 1995b] and can induce geochemical signatures for plume-ridge separation distances of nearly 1500 km [Schilling, 1991]. The "mantle-plume source/migrating ridge sink" model of Schilling and co-workers suggests that migrating ridges are "fed and dynamically affected by a preferential plume flow along a thermally induced channel at the base of the lithosphere" [Schilling, 1991]. This model suggests that a thermal channel is progressively carved into the lithosphere as the ridge migrates over and away from the impinging hot plume [Morgan, 1978; Schilling, 1985; Schilling et al., 1985]. All of the 13 plume ridge systems considered by Schilling [1991] have ridges migrating away from their nearby plumes in support of this plume source-migrating ridge sink model.

Recent numerical modeling and laboratory experimental studies have begun to characterize the kinematic and dynamic aspects of the interaction between mantle plumes and stationary midocean ridges. For ridge-centered plumes, scaling laws for the dependence of along-axis plume width \( W \) on plume volume flux \( Q \) and ridge full spreading rate \( U \) were first explored in tank experiments [Feighner and Richards, 1995] and further developed in numerical studies [Feighner et al., 1995; Ribe et al., 1995; Ito et al., 1996]. The dynamics of off-axis plumes were first investigated in the laboratory by Kincaid et al. [1995a] and in 2-dimensional (2-D) numerical experiments by Kincaid et al. [1995b]. Finally, Ribe's [1996] study of off-ridge plumes established scaling laws for the dependence of \( W \) on a range of variables including \( Q, U \), plume-ridge distance \( x_p \), and lithospheric thickening with age.

While the above studies established scaling parameters of plume ridge interaction they did not investigate the effects of ridge migration. In the more realistic case of a migrating ridge, not only may thermal thinning of the lithosphere be important as proposed by
Schilling's and co-worker's plume source-ridge sink hypothesis, but also the plate trailing the migrating ridge moves significantly slower than the plate leading the ridge, thereby inducing less drag on the plume away from the ridge [Ribe, 1996].

We here explore the dynamics of migrating ridges and plumes with 3-D numerical models that include thermal diffusion and fully pressure- and temperature-dependent rheology. We will first establish scaling laws for along-axis plume width \( W \) and maximum plume-ridge interaction distance \( x_{111} \) for steady-state systems of stationary ridges. These results will be compared with those of the chemically buoyant, constant viscosity plume models of Ribe [1996] first to verify the scaling parameters and then to quantify the importance of thermal diffusion and variable plume viscosity on these scaling laws. We will then quantify the effects of ridge migration on \( W \) and \( x_{max} \) and identify the physical mechanisms controlling this plume source-migrating ridge sink model. Finally, we will test our models by comparing model predictions with geophysical observations of the Galápagos plume-migrating ridge system, and then discuss the implications for the dimensions, temperature anomaly, volume flux, and geochemical signature of the Galápagos plume.

**GOVERNING EQUATIONS AND NUMERICAL METHOD**

The mantle is modeled as a viscous Boussinesq fluid of zero Reynolds number and infinite Prandtl number. The equilibrium equations include conservation of mass

\[
\nabla \cdot u = 0, \quad (1)
\]

momentum

\[
\nabla \cdot \tau = \Delta \rho g, \quad (2)
\]

and energy

\[
\frac{\partial T}{\partial t} = \kappa \nabla^2 T - u \cdot \nabla T \quad (3)
\]

(see Table 1 for definition of variables). Mantle density \( \rho \) is reduced by thermal expansion such that \( \Delta \rho = \rho_0 \alpha \Delta T \), and the 3-D stress tensor \( \tau \) depends on the strain rate tensor \( \dot{\varepsilon} \) according to \( \tau = 2\eta \dot{\varepsilon} - pI \). Viscosity \( \eta \) depends on pressure \( p \) and real temperature \( T_R \) according to.

\[
\eta = \eta_0 \exp \left\{ \frac{E + pV}{RT_R} - \frac{E + \rho_0 g(0.5D)V}{RT_{Ro}} \right\} \quad (4)
\]
in which $T_{R0}$ is the real temperature of the mantle at $z = 0.5D$. Reduced values of $R$ and $V$ are used to simulate numerically the behavior of a non-Newtonian rheology (i.e. $\dot{\varepsilon} \propto r^3$) [Christensen, 1984]. The ratio of ambient/plume viscosity $\gamma$ is defined as $\eta_0/\eta_p$, where $\eta_p$ is the viscosity of the plume at $z = 0.5D$.

Calculations were done using the Cartesian numerical code first written by Gable [1989] and Gable et al. [1991], and later modified by Ito et al. [1996] to incorporate variable viscosity. The numerical setup is illustrated in Fig. 1. Two spreading plates are simulated by imposing surface horizontal velocities of $u_x = +U/2$ and $u_x = -U/2$ on both sides of a model ridge axis. A plume is introduced by imposing a columnar-shaped temperature anomaly in the lower portion of the box at a distance $x_p$ from the ridge axis. The plume source is hottest ($T = T_0 + \Delta T_p$) at its center and cools as a Gaussian function of radial distance to $T_0$ at its full radius. The vertical sides of the box are free of shear stress and have zero horizontal temperature gradient. Therefore, the symmetry introduced by the reflecting side boundaries allow this half-of plume-ridge system in numerical models to simulate a full plume-ridge system in virtual space. Temperature at the surface is maintained at $0^\circ$C which cools and thickens a high viscosity lithosphere approximately with the square root of distance from the ridge axis. Temperatures in the lower portion of the box ($z > 0.6D$) are maintained at the reference mantle potential temperature $T_0$ everywhere except inside the plume source. Correspondingly, the energy equation is solved in only the upper portion of the box ($0.6D \leq z \leq 0$). The purpose of the lower volume of the box is to simulate an open boundary at the base of the upper volume where the plume-ridge interaction occurs. To ensure numerical accuracy of the flow solutions, we limit the horizontal viscosity variation to be $< 10^3$ by defining an upper viscosity limit for the lithosphere depending on the viscosity of the hot plume.

To track the flow of the mantle plume, we introduce a passive tracer $P$ in the plume source with value of 1.0 to represent 100% plume material. A finite difference, tensor diffusion method [Gable, 1989; Travis et al., 1990] is used to solve for advection of $P$, from the source and throughout the upper volume of the box ($z < 0.6D$). Diffusion of $P$ is required by our numerical method but the rate of diffusion is reduced by a factor of 3 relative to the rate of thermal diffusion. $P$ is also used to determine along-axis width of the plume by measuring the along-axis distance over which the mean value of $P$ beneath the
Finally, we use \( P \) in the steady-state stationary ridge case, to measure the volume flux of plume material crossing the ridge axis by integrating horizontal velocities on the side of the ridge opposite the plume where \( P > 0.4 \). The volume flux of the plume source \( Q \) is measured by integrating vertical velocities at \( z = 0.6D \) over the cross-sectional area of the source column.

**SCALING LAWS FOR STATIONARY RIDGES**

Feighner and Richards [1995] and Feighner et al. [1995] demonstrated that \( W_o = (Q/U)^{1/2} \) is an effective length scale for characterizing the horizontal dimension of a ridge-centered, gravitationally spreading plume. They also defined a plume buoyancy number \( \Pi_b = Q\alpha U^2 \) where \( \alpha = g\Delta \rho/48\eta_o \), which characterizes the relative strength of gravitational versus plate-driven spreading. Subsequent analyses of Ribe et al. [1995] derived a characteristic plume thickness scale \( S_o = (Q/\sigma)^{1/4} \), which determines \( \Pi_b \) according to \( \Pi_b = (W_o/S_o)^4 \). The effect of the sloping lithosphere on the interaction of off-axis plumes was characterized with the "upslope number" \( \Pi_u = Q^{1/8}\alpha^{3/8}k^{1/2}/U \) by Ribe [1996].

The above scaling quantities were shown by lubrication theory models of Ribe [1996] to define a full scaling law of along-axis width \( W \) for steady-state stationary ridges,

\[
W = W_o F_1(\Pi_b) F_4(\Pi_b, \Pi_u) F_3\left(\frac{x_p}{W_o}, \Pi_b, \Pi_u\right).
\]

Functions \( F_1 \) and \( F_4 \) describe the increase in steady-state width with increasing values of \( \Pi_b \) and \( \Pi_u \), for ridge-centered plumes \((x_p = 0\)\); whereas function \( F_3 \) describes the first-order dependence of \( W \) on plume-ridge separation distance \( x_p \) and the second-order dependence on \( \Pi_b \) and \( \Pi_u \). We now further investigate this scaling law with numerical models that include both thermal diffusion and temperature-dependent plume viscosity.

**Ridge-centered plumes**

The simplest case is that of a ridge-centered plume. In this case \( x_p = 0 \) and \( F_3 = 1.0 \), therefore we seek to define functions \( F_1 \) and \( F_4 \). In our numerical experiments, we vary full spreading rate \( U \) between 20 and 120 km/m.y. and modulate plume flux \( Q \) by varying plume temperature anomaly \( \Delta T_p \) between 100 and 200°C (see Table 2). Three models of
plume viscosity structure are examined. The first is designed to simulate the constant plume-viscosity calculations of Ribe [1996]. This viscosity structure omits the pressure-dependence of Eq. 4 and has \( \eta = \eta_0 \) for \( T \geq T_o \), thus plume viscosity is the same as the ambient fluid (\( \gamma = 1.0 \)). To allow for a thickening lithospheric boundary layer, we incorporate the temperature-dependence in Eq. 4, for \( T < T_o \). The second and third viscosity models have the full pressure- and temperature-dependence as defined by Eq. 4; the second has \( \gamma = 2.352 \) for \( \Delta T_p = 100^\circ C \), and the third has \( \gamma = 5.053 \) for \( \Delta T_p = 200^\circ C \).

A scaling law for normalized plume width \( W/W_o \), which defines \( F_1 \), is determined by fitting \( W/W_o \) to exponential functions of the quantity \( \Pi_b \gamma \), a modified buoyancy number defined by the viscosity of the plume [Ito et al., 1996]. \( W/W_o \) is described well by the function

\[
\log_{10}(W/W_o) = 0.32 + 0.01[\log_{10}(\Pi_b \gamma)] + 0.05[\log_{10}(\Pi_b \gamma)]^2
\]

with a standard deviation misfit of 8% of the median value of 2.25 (Fig. 2). This function is consistent in general form with Ribe's [1996] results of \( \log_{10}(W/W_o) = 0.217 + 0.0569[\log_{10}(\Pi_b \gamma)] + 0.0176[\log_{10}(\Pi_b \gamma)]^2 + 0.0275[\log_{10}(\Pi_b \gamma)]^3 \). The relatively weak dependence of \( W \) on \( \log_{10}(\Pi_b \gamma) \) in our results may reflect our source radius of finite width, which becomes comparable to \( W_o \) at low values of \( \Pi_b \gamma \) and thus contributes to along-axis width in a manner unlike by Ribe's [1996] point source plumes. In addition, we are unable to identify a dependence on \( \Pi_u \) which is described by Ribe's [1996] function \( F_4 = (1 + 1.77 \Pi_u \Pi_b^{-0.33}) \).

**Off-axis plumes**

To derive scaling laws for off-axis plumes, we seek to define the function \( F_3 \). Fig. 3 illustrates the shape of the plume at different distances from the ridge axis. When the plume is ridge-centered, it spreads along the ridge-axis, is divided by the spreading plates, and then spreads symmetrically away from the ridge axis. When it is off the ridge, the plume spreads asymmetrically beneath the moving plate with the upwind side tapering towards the ridge and the downwind side widening away from the ridge as it is sheared away by the moving plate. The ridge thus captures a narrower width of the plume as \( x_p \) is increased. If \( x_p \) is large enough, the ridgeward flowing plume material stagnates against the migrating plate as investigated by Sleep [1987] and Ribe and Christensen [1994]. It is this stagnation distance that defines the maximum distance to which plume material will contact the ridge axis, \( x_{\text{max}} \).
Function $F_3$ is the dependence of $W$ on plume-ridge distance and is equivalent to $W/W(x_p=0)$ (Eq. 5). Fig. 4a shows numerical results of $F_3$ versus $x_p/W_0$. The best fitting function is a binomial function of the form

$$F_3 = [1.0 - 0.68(x_p/W_0 F_2)^2]^{1/2}$$

as consistent with that of Ribe [1996]. As evident in Fig. 4a, cases with $\gamma = 1.0$ yield the shortest distances of plume-ridge interaction, whereas increasing values of $\gamma$ result in greater distances of plume-ridge interaction. This second order variation in plume width reflects a stretching function $F_2$, which depends primarily on $\gamma$ and secondarily on $\Pi_b$ with a best fitting function

$$F_2(\Pi_b\gamma) = (\Pi_b\gamma)^{0.01}\gamma^{0.14}.$$ 

As illustrated in Fig. 4b, $F_2$ collapses values of $W/W(x_p=0)$ on to a single curve. Thus the combined Eqs. 7 and 8 describe effectively the dependence of $W$ on plume ridge distance for steady-state cases. The primary dependence of $F_2$ on $\gamma$ may indicate that not only do less viscous plumes spread more gravitationally, but also they are subject to less shearing from the overlying migrating plate. The increase in $x_{\text{max}}$ with $\gamma$ as predicted here is consistent with results of 2-D experiment by Kincaid et al. [1995b]. $F_2$ derived from our numerical models captures the linear exponential term of Ribe's [1996] function,

$$\log_{10}(F_2) = 0.043[\log_{10}(\Pi_b)] + 0.060[\log_{10}(\Pi_b)]^2 - 0.0062[\log_{10}(\Pi_b)]^3;$$

however, our results show a weaker dependence on $\Pi_b$. We again do not observe a strong dependence of $F_3$ on $\Pi_u$ over the range of $\Pi_u$ examined.

We also investigate the percentage of the plume flux that crosses the ridge axis $Q_r$. For ridge-centered cases, half of the plume material flows to each side of the ridge such that $Q_r = 0.50$. As the plume moves away from the ridge axis, $Q_r$ decreases according to

$$Q_r = 0.50 - 0.41(x_p/W_0 F_2)$$

as illustrated in Fig. 5. This function is again similar to that of Ribe's [1996], $Q_r = 0.50 - 0.79p + 0.24p^2$, where $p = (x_p/W_0 F_2)$.

Functions $F_3$ and $Q_r$ (Eqs. 7 and 9) are zero when $x_p = x_{\text{max}}$, and consequently

$$x_{\text{max}} = 1.21W_0F_2.$$ 

For the case of $\gamma = 1.0$, our predicted values of $x_{\text{max}}/W_0$ are ~50% greater than those predicted by Ribe [1996]. Some of this discrepancy may be due to differences in numerical models; for example our finite source radius versus Ribe's [1996] point source as mentioned earlier. Another potentially important cause of this discrepancy may be thermal erosion of the lithosphere. Fig 6. illustrates the thickness of the lithosphere that was eroded by the plume scaled by the modified characteristic plume thickness $S_0\gamma^{-1/4}$ =
The greatest erosion occurs downwind of the plume where the plume has been in contact with the lithosphere the longest. The downwind slope of the channel acts to inhibit ridgeward spreading as noted by Kincaid et al. [1995a,b]; however, our results suggest that the dominant effect is the slope of the channel in the y-direction which enhances spreading toward the ridge by inhibiting spreading in the along-axis direction. Ribe [1996] predicted this effect to enhance $W$ by $\sim 10\%$.

The similarities between the above scaling laws for ridge-centered and off-axis plumes and those of Ribe [1996] indicate that the general form of these scaling laws are robust and insensitive to differences in far field boundary conditions. The additional physics we include are variable plume viscosity and thermal erosion, both of which enhance $W$ at a given value of $x_p$ as well as the total range over which an off-axis plume interacts with a nearby stationary ridge.

**SCALING LAWS FOR MIGRATING RIDGES**

To derive scaling laws for the case of a migrating ridge we simulate a ridge moving in the positive $x$-direction at velocity $V_r$. With respect to the ridge, both plates are assumed to spread symmetrically at a rate of $U/2$; therefore with respect to the plume, Plate 1 (the leading plate moving in the positive $x$-direction) spreads with velocity $+U/2 + V_r$ and Plate 2 (the trailing plate moving in the negative $x$-direction) spreads with velocity $-U/2 + V_r$ (Fig. 7). These velocity conditions are incorporated by defining the appropriate horizontal velocities of the surface boundary, whereas the motion of the ridge is simulated by redefining the $x$-position of the diverging surface velocities at each step during time integration.

Numerical experiments began with the steady-state configuration of a plume and stationary ridge, with the plume beneath Plate 1 at $x_p > x_{max}$. We then allowed the ridge to migrate toward, over, and away from the plume such that the plume ends up beneath Plate 2. We use the convention, $x_p > 0$ when the plume is beneath Plate 1 and $x_p < 0$ when the plume is beneath Plate 2. Three ridge migration velocities are tested for parameters of experiments 3, 5, 7, 8, and 12 (Table 2). In each case, the maximum $V_r$ examined is equal to the half spreading rate.

The dependence of $W$ on $x_p$ is shown in Fig. 8 for experiment 7. The form of the function of $W$ versus $x_p/W_o$ is the same as that of $F_3$ in Eq. 7, but the curves are shifted.
increasingly in the negative $x_p$-direction with increasing $V_r$, and the total range over which the plume interacts with the ridge broadens with $V_r$. $F_3$ is thus modified to

\[
F_3 = \left[ 1.0 - 0.68F_6(s,\Pi_b\gamma) \left( \frac{x_p}{W_o + F_5(s,\Pi_b\gamma)} \right) \frac{F_2(s,\Pi_b\gamma)}{F_2(s,\Pi_b\gamma)} \right]^{1/2}, s=(2V_r/U). \tag{11}
\]

Function $F_5$ describes the shift of the curves in the negative $x_p$-direction and is best fit by the function

\[
F_5 = 0.39(\Pi_b\gamma)^{-0.12}(2V_r/U) \tag{12}
\]

(Fig. 9a). Function $F_6$ controls the increase in total range of plume-ridge interaction and is best fit by the function

\[
F_6 = 1.0 - 0.17(\Pi_b\gamma)^{-0.12}(2V_r/U)^{1/2} \tag{13}
\]

(Fig. 9b).

Function $F_5$ reflects largely the differential shearing of the plume by the asymmetrically moving plates and has the largest effect on the range of plume ridge interaction. When $x_p > 0$, the plume's upwind stagnation point defines the maximum distance to which the plume interacts with the ridge. The faster moving Plate 1 induces more drag on the plume away from the ridge (Fig. 7a) therefore pushing the stagnation point closer to the plume source and reducing $x_{\text{max}}$ relative to the case in which $V_r = 0$. When $x_p < 0$, the plume separates from the ridge when the ridgeward spreading velocity of the plume drops below the migration rate of the ridge. The slower moving Plate 2 induces less shear away from the ridge (Fig. 7b), consequently, the plume is able to keep up with the migrating ridge over a greater distance. $F_5$ reduces $x_{\text{max}}$ for $x > 0$ and increases $x_{\text{max}}$ for $x < 0$ by as much as 35% of $x_{\text{max}}$ for a stationary ridge. The degree to which the differential motion of the two plates is able to alter the shape of a plume diminishes for strong plumes. This is reflected in the inverse relationship between $F_5$ and $\Pi_b\gamma$.

Function $F_6$ most likely reflects the effects of lithospheric erosion, which increases the total range over which the plume interacts with the ridge. Thermal erosion has the strongest effect on the system after the ridge has migrated over and away from the plume (Fig 10) as hypothesized by Schilling [1991]. In the case that $V_r$ is small (Fig. 10a), the velocity of Plate 2 is largest thus allowing the plume to erode a greater area of the plate downwind of plume source. Consequently, the plume spreads more easily away from the ridge through the downwind eroded channel. On the other hand, when $V_r$ is larger (Fig. 10b and 10c), Plate 2 moves slower, and the downwind channel is more confined to the
plume source, thereby enhancing spreading toward the ridge. The dependence of \( F_6 \) on \( 2V_r/U \) weakens, however, with increasing \( \Pi_b \gamma \) because the shape of the overlying lithosphere has less effect on gravitational spreading of the plume at higher values of \( \Pi_b \gamma \). For \( V_r = U/2 \), \( F_6 \) increases the total range of plume ridge communication by an average of 11%.

Thus, lithospheric erosion has only second-order importance in influencing the flow of near-ridge plumes—a result that differs from that envisioned in Schilling and co-worker’s plume source-migrating ridge sink model. The effects of the lithosphere are likely to be weakest when the characteristic plume thickness \( S_0 \gamma^{-1/4} \) is large relative to the thickness of the lithospheric boundary layer. Indeed, the values of \( S_0 \gamma^{-1/4} \) examined here are 100-150 km—3-5 times the thickness of the lithosphere overlying the plumes. The regime in which \( S_0 \gamma^{-1/4} \) is comparable to the thickness of the lithosphere would allow the lithosphere to influence more strongly the ability of the plume to spread to the ridge. This low-\( S_0 \gamma^{-1/4} \) regime would require significantly hotter plumes to reduce \( \eta_p \), as well as significantly narrower sources radii to limit \( Q \). Such conditions, however, may be unusual in the Earth given that the 50-km radius and 100-200°C temperature anomalies examined here are reasonable properties of Earth plume examples [e.g. Ito and Lin, 1995b; Schilling, 1991; Wolfe et al., 1996].

Our complete scaling law for plume width and migrating ridge is thus

\[
W = W_o F_1(\Pi_b \gamma)
\begin{pmatrix}
1.0 - 0.68 F_6(s, \Pi_b \gamma) \left( \frac{W_o + F_5(s, \Pi_b \gamma)}{F_2(s, \Pi_b \gamma)} \right) \\
\end{pmatrix}^{1/2},
\]

and our complete our scaling law for the maximum plume-ridge interaction distance is

\[
x_{max} = (\pm 1.21 F_2 F_6^{1/2} - F_5) W_o.
\]

Ridge migration has first order effects on the dynamics of plume-ridge interaction. On average, ridges migrating toward plumes at rates comparable to their half spreading rates, can sample plume material over distances ~24% less than stationary ridges. Ridges migrating away from plumes at rates comparable to their half spreading, however, are able to sample plume material to plume-ridge distances ~36% greater than stationary ridges and almost twice as far as ridges migrating toward plumes.

**THE GALÁPAGOS PLUME-MIGRATING RIDGE SYSTEM**
We compare model predictions with observations at the Galápagos plume and spreading center, a classic and relatively well studied example of an off-axis plume-migrating ridge system (Fig. 11). The Galápagos spreading center separates the Cocos plate to the north and the Nazca plate to the south with a full spreading rate of $\sim 55$ km/m.y. at 91°W [DeMets et al., 1994]. The ridge is currently migrating northward with respect to the hotspot at a rate of 27 km/m.y. [Gripp and Gordon, 1990], which is $\sim 1$ km/m.y. less than the half-spreading rate. Ito and Lin [1995a] documented that the total amplitude of bathymetric and mantle-Bouguer gravity anomalies (MBA) along Cocos Plate isochrons increase with isochron age, and suggested that this behavior reflects increased crustal production in the past when the plume was closer to the ridge. Our purpose here is to compare predicted and observed profiles of bathymetry and MBA in order to assess the degree to which the models can explain the observations and to place theoretical constraints on the dimensions, temperature anomaly, and flux of the Galápagos plume.

Calculations of crustal thickness, bathymetric, and gravity anomalies

Because 70-75% of the along-isochron bathymetric and gravity variations most likely arise from plume induced thickening of the igneous crust [Ito and Lin, 1995a], crustal thickness calculations are a crucial link between our fluid dynamic models and surface observations. To predict crustal thickness along a model ridge axis, we incorporate the solidus and liquidus functions of McKenzie and Bickle [1988], as well as their functional dependence of melt fraction $M$ on homologous temperature for adiabatic batch melting. Assuming melt generated in the mantle accretes perpendicularly to the ridge axis, crustal thickness along the ridge is calculated according to

$$Cr(y) = \frac{1}{U} \left( \frac{\rho_o}{\rho_m} \right) \int \dot{M}(x,y,z) dx dz$$

where $\dot{M} = \frac{\partial M(p,T)}{\partial t}$. This method generates a normal ridge crustal thickness of 6.5 km with the assumed ambient mantle temperature $T_o$ of 1300 °C. Because the Galápagos plume enhances crustal production at the ridge as well as generates Galápagos Islands, an important source of uncertainty is how melt produced by the plume is partitioned between the ridge and hotspot islands. We do not attempt to model melt migration from the mantle to the ridge and islands, but instead, we assume that all melt generated closest to the ridge
axis accretes at the Galápagos Spreading Center and all melt generated closest to the plume source accretes at the Galápagos Islands. Crustal thickness along the ridge and at the hotspot therefore change with time as a direct result of the position of the ridge and plume source. For this reason we compare not only predicted and observed anomalies at the Galápagos Spreading Center but also crustal production rates of the Galápagos Archipelago.

When considering melting, it is important also to account for its effects on the mantle [Ito et al. 1996]. Melting reduces mantle temperature due to latent heat loss, which increases both mantle density and viscosity; but at the same time, melting reduces mantle density by preferential extraction of iron with respect to magnesium [Oxburgh and Parmentier, 1977]. Latent heat loss is incorporated by introducing a source term \(-T\Delta S/c_p\) in the energy equation (Eq. 3). The compositional effect on mantle density is incorporated by the equation

\[ \Delta \rho = \rho_0 (\alpha T + \beta X), \]

where \(X\) is the extent of melt depletion and \(\beta = 0.24\) is a coefficient of depletion density reduction [Oxburgh and Parmentier, 1977]. The equilibrium equation for the depletion field is

\[ \frac{\partial X}{\partial t} = -u \cdot \nabla X + \dot{M}, \]

in which the advection term is solved using the same tensor diffusion method as that used to solve for temperature field, and the source term \(\dot{M}\) is solved as described above. The above melting effects do not modify significantly the broad scale flow of the plume [Ito et al. 1996]; however, they contribute substantially to the mantle contributions to bathymetric and gravity anomalies.

To calculate isostatic topography of the seafloor, we consider contributions from both the crust and mantle. In calculating crustal topography, we assume Airy-type compensation of the crust assuming a normal crustal density of 2700 kg/m³ that increases linearly along axis to \(\rho_{max}\) within 500 km of the point closest to the hotspot (-91°W). Values of \(\rho_{max}\) considered are 2900 and 3000 kg/m³. In calculating topography due to the mantle, we assume Pratt-type compensation with a compensation depth of 200 km and include both thermal and compositional density effects as defined in Eq. 17.

Mantle-Bouguer gravity anomaly (MBA) is the free-air gravity minus the attraction due to topography of the seafloor and crust-mantle interface assuming a reference crust of
uniform density (e.g., 2700 kg/m³) and thickness (e.g., 6.5 km) [e.g. Kuo and Forsyth, 1988; Lin et al., 1990]. MBA therefore reflects crustal thickness structure that differs from this reference crust as well as variations in mantle density. To calculate MBA, we again include the contribution of along-axis crustal thickness variations, and thermal and compositional mantle density variations [Ito et al. 1996].

We investigate two radii and temperature anomalies for the Galápagos plume source: one has a radius of 100 km and temperature anomaly $\Delta T_p$ of 80°C, and the other has a radius of 80 km and $\Delta T_p$ of 120°C. Both plume source models predict comparable volume fluxes of 4.5x10⁶ km³/m.y.—a value slightly greater, but comparable to the prediction of 2.6-3.6 km³/m.y. by Schilling [1991] and the 2.2x10⁶ km³/m.y. lower-bound prediction of Ito and Lin [1995b]. Values for $T_o$ of 1300 °C and $\eta_o$ of 3 x 10¹⁹ Pas yield a Rayleigh number of 3.05 x 10⁶. We began model calculations began with a steady-state condition of the plume beneath Plate 1 (Cocos Plate). We then activated ridge migration and tracked crustal production and mantle evolution as the ridge migrated over the plume source. Calculations finished with Plate 2 (the Nazca Plate) over the plume source and when the ridge was 200 km from the plume source. This distance is the average distance between Fernadina Island and the two ridge segments east and west of the transform fault at 91°W (Fig 11).

**Predicted and observed bathymetric and gravity anomalies**

Model predictions of bathymetry and MBA are compared with five along-isochron profiles investigated by Ito and Lin [1995a]: the present-day ridge axis and isochrons at crustal ages of 2.6, 3.6, 6.0, 6.6, and 7.7 m.y. Hey [1977] suggested that the Galápagos Spreading Center was centered over the plume ~10 Ma. Therefore, we associated model crustal profiles with isochrons by taking the crustal profiles generated with $x_p$ values that were the same fractions of 200 km as each isochron was of 10 m.y. For example the 3.6 Ma isochron was assumed to have formed when the plume was 36% closer to the ridge than it is today, i.e., $x_p = 128$ km. Mantle bathymetric and gravity profiles were extracted at x-positions on Plate 1 (Cocos Plate) corresponding directly to the isochron ages. The total predicted bathymetric and MBA anomaly profiles are the sum of the crustal and mantle contributions.

The comparisons between model and observed profiles in bathymetry are shown in Fig. 12 for $\rho_{max} = 2900$ kg/m³. Along the present day ridge axis and isochrons younger than 6 m.y., both models predict reasonably well the amplitudes and wavelengths of the
observations. Along isochrons older than 6 m.y., the cooler plume source of model 1 also yields predictions consistent with the observations but the hotter plume source of model 2 over-predicts the bathymetric anomalies.

The similar anomaly amplitudes predicted by the two models at the youngest isochrons (i.e., 200 km ≥ x_p ≥ 128 km) reflects the similarity between the amount of melt partitioned to the axial crust despite the differences in plume source properties. Although the cooler plume source of model 1 is predicted to generate less total melt than the hotter source of model 2, the greater radius of the model 1 plume source causes more melting to occur near the ridge axis, thus, a larger percentage of the total melt liberated is partitioned to the ridge. On the other hand, the narrower source of model 2 predicts melting to be more localized to the center of the plume source, therefore, a smaller percentage of the total melt generated is partitioned to the ridge axis. This trade-off between source radius and temperature explains why at the younger isochrons, the two different plume sources yield similar crustal thicknesses at the ridge axis. Along the oldest three isochrons (i.e., 128 km > x_p ≥ 40 km), however, the differences between the bathymetric predictions of models 1 and 2 are greatest because the amount of melt partitioned to the ridge crust reflects a larger percentage of the total melt produced. Consequently, the hotter source model (model 2) over predicts the crustal thickness at the ridge axis.

While the difference between the two source temperature anomalies is but slight, the differences between predicted crustal thickness anomalies at the three oldest isochrons is substantial: model 2 predicts crustal thickness anomalies of 11-15 km, about twice as large as the 6-8 km-anomalies predicted by model 1. These large differences in predicted crustal thickness anomalies reflects the high sensitivity of upwelling thus melting rate to plume temperature anomaly due to the combined effects of reduced viscosity and enhanced thermal and depletion buoyancy. Directly above the plume source, model 2 predicts a maximum upwelling rate 250 km/m.y. This rate is nearly twice as high as that predicted by model 1 of 140 km/m.y., thus explaining the factor of two difference between the model 2 and model 1 crustal thickness anomalies at the three oldest isochrons.

Directly beneath the plume-affected portion of the present-day ridge axis (i.e. directly north of the plume), however, both models 1 and 2 predict a ~30% reduction of upwelling/melting rate relative to that beneath the unaffected portions of the ridge; the reason being, is that upwelling that normally accommodates plate spreading is replaced by lateral flow supplied by the plume. A significant proportion the melting that contributes to ridge axis crust at the present-day, is therefore predicted to occur near the midpoint between
the plume source and the Galápagos Spreading Center. The maximum extent of melting predicted at present-day is 23% for model 1 and 26% for model 2.

Because crustal thickness at the ridge is predicted to increase with isochron age, the contribution to bathymetry of the crust relative to that of the mantle also is predicted to increase. Model 1, for example, predicts a crustal uplift at the present-day ridge axis of 0.6 km, which is 60% of the predicted total anomaly of 1.0 km. In contrast, along the 7.7-m.y. isochron, model 1 predicts a crustal uplift of 1.2 km, which is 80% of the predicted total bathymetric anomaly of ~1.5 km. Likewise, model 2 predicts a crustal uplift along the present-day ridge of 0.6 km, which is 50% of the total anomaly of 1.2 km, and a crustal uplift along the 7.7-m.y. isochron of 2.4 km, which is 80% of the total predicted anomaly of ~3.1 km. These predictions are consistent with the gravity and bathymetry analyses of Ito and Lin [1995a] which suggested that the depth of compensation shallows with increasing isochron age.

Comparisons between predicted and observed MBA profiles are shown in Fig 13. Similar to the results of the bathymetry comparisons, both models 1 and 2 yield MBA amplitudes and widths consistent with the observations for the three youngest isochrons, but model 2 over-predict the amplitudes of the MBA at the three oldest isochrons. In model 1, the crustal component of MBA is predicted to be 65% of the total predicted anomaly of -80 mGal at the present-day ridge axis and ~82% of the -140-mGal anomaly predicted along the 7.7-m.y. isochron. Lateral density variations in the mantle supply the remaining proportions of the anomalies. In model 2, the crustal contribution to MBA is predicted to be 55% of the total predicted anomaly of -94 mGal along present-day ridge axis and 80% of the total predicted anomaly of -261 mGal along the 7.7-m.y. isochron. Thus, for both along-isochron MBA and bathymetric anomalies, the relative contribution of the crust is predicted to be 50-80% of the total anomalies—a range slightly greater than the estimates of Ito and Lin [1995a] who used a passive mantle upwelling model.

The predicted and observed amplitudes of along-isochron MBA and bathymetric anomalies for both $\rho_{max} = 2900$ and 3000 kg/m$^3$ are plotted versus isochron age in Fig 14 (a) and (b). For the youngest isochrons, the observed amplitudes appear to be matched best by predictions of the hotter source of model 2 with the upper-bound $\rho_{max}$ of 3000 kg/m$^3$. For the oldest isochrons, the observed anomaly amplitudes are best matched by the cooler source of model 1, but again with $\rho_{max}$ of 3000 kg/m$^3$. Model 2 yields upper-bound predictions for the oldest isochrons. In general, the observed anomaly amplitudes
are bracketed by the predictions resulting from the range of $\rho_{max}$ as well as source radii and temperatures considered.

**Galápagos Archipelago crustal volume flux**

As discussed above, because of the large uncertainty in evaluating how melt is partitioned between the ridge crust and hotspot islands we must consider also the crustal production rate at the Galápagos Archipelago. We first estimate the total volume of the Galápagos Archipelago by assuming the observed bathymetry is supported by Airy isostasy of the crust. We consider the bathymetry in the white box in Fig. 11, the longitudinal extent of which corresponds to ~10 m.y. of island accretion [Sinton et al., 1996]. Lithospheric flexure [Feighner and Richards, 1994] is neglected here because flexure acts to only smooth topography of the crust-mantle interface but does not affect the total volume of the compensating crustal root. To correct for the long wavelength swell topography, which is unlikely to reflect island volcanism, we subtract a reference depth plane with the box's average bathymetric slope in both longitudinal and latitudinal directions. From this residual bathymetric map, we calculate the isostatic thickness of the Galápagos Archipelago and then integrate along latitudinal profiles to derive excess crustal volume as a function of longitude across the box (the mean thickness of a normal oceanic crust of 6.5 km is excluded). Each longitude is then assigned an age assuming a constant eastward migration rate of the Nazca Plate relative to the plume. Finally, we estimate crustal volume flux as a function of age by dividing the estimated volumes by the time spans represented by their spacing in longitude. To be consistent with the assumed values of $\rho_{max}$ along the ridge axis, we consider island crustal densities of 2900 and 3000 kg/m$^3$.

Fig. 14c shows the estimated island fluxes through time which yield averages of $1.2 \times 10^5$ and $1.6 \times 10^5$ km$^3$/m.y. over the past 7.7 m.y. for crustal densities of 2900 and 3000 kg/m$^3$ respectively. Similar to the comparisons of the isochron anomalies, the hotter plume source in model 2 predicts an island crustal flux most consistent with the calculated fluxes over the most recent 4 m.y. and an upper-bound for the island flux at times $> 4$ Ma. The cooler plume source of model 1, on the other hand, predicts lower-bound island fluxes over the most recent 4 Ma and fluxes that are more consistent with the estimated fluxes at times $> 4$ Ma. In general, the range of source temperatures and radii considered by our two models yield island fluxes consistent with those estimated from the bathymetry of the Galápagos Archipelago.
It is possible that the Galápagos plume source may have changed through time in temperature anomaly, radius, or both as hinted by the closer match of the hotter source model to observations associated with crustal ages < 4 Ma and closer match of the cooler source model to observations associated with crustal ages > 4 Ma. However, given the range of uncertainties in our models it is impossible to resolve such changes in source properties. The conclusions we make are that our numerical plume-ridge models are capable of explaining the first order variations in ridge-axis anomalies and island flux estimates at present-day, as well as explaining the apparent evolution over the past ~8 m.y.

A potentially important test of our models would be a mantle teleseismic study of the Galápagos plume-ridge system, which would test directly our predictions of source dimension and temperature anomaly. Beneath the Galápagos Archipelago, we predict a P-wave velocity reduction of 0.5-0.7% due to the excess temperature of the plume and up to 2% in the melting region if there is up to 3% of melt present in the mantle [Ito et al., 1996]. This prediction is based on a 6.25x10^{-3}% reduction of P-wave velocity for each 1°C temperature anomaly and a 1.25% decrease in velocity for each 1% porosity of melt in the mantle [Humphreys and Dueker, 1994]. Such velocity anomalies are predicted to result in a 0.3-0.4 s delay over the center of the hotspot for P-waves passing vertically through the upper 400 km of mantle we have modeled. Along the Galápagos Spreading Center, however, we predict mantle P-wave velocities to actually increase by up to 0.5% in the melting zone relative to normal ridge mantle. The reason for this velocity increase is that the plume material feeding the ridge has already experienced melting at the hotspot; consequently, the velocity enhancing effects of melt depletion (0.1% velocity increase for each 1% degree of depletion [Humphreys and Dueker, 1994]) dominate over the velocity reducing effects of temperature and melt retention directly beneath the ridge. Another valuable study would be to obtain seismic constraints on crustal thickness variations along the ridge axis and along the seafloor isochrons. This study would test directly our predictions of along-isochron crustal thickness variations and place hard constraints for geodynamic models such as these.

**Geochemical implications**

Much of the original observations that led to the concept that plumes feed nearby ridges comes from systematic variations in basalt chemistry. Schilling and co-workers noted that Galápagos ridge axis basalts erupted nearest the Galápagos hotspot have compositional affinities to ocean island basalts (OIB)—being enriched relative to midocean ridge basalts
(MORB) in radiogenic isotopes [Verma and Schilling, 1982; Verma et al., 1983] and incompatible rare-earth and major elements [Schilling et al., 1976; Schilling et al., 1982]. They showed that the OIB signatures decrease along the ridge axis with increasing distance from the hotspot. An example of this behavior is revealed in La/Sm ratios as shown in Fig. 15. Such a systematic decrease in the OIB signature is interpreted to reflect mixing between the OIB plume source with the MORB upper mantle source material.

To investigate the processes of plume and ambient mantle mixing, we calculate the amount of plume tracer \( P \) composing the model crust along the ridge. After Ito et al. [1996], the average plume tracer concentration in accumulated melts as a function of along-axis coordinate is

\[
\bar{P}(y) = \frac{\int P(x,y,z)M(x,y,z)dx\,dz}{\int M(x,y,z)dx\,dz},
\]

By the definition, \( \bar{P} = 1.0 \) indicates that all melts generated in a plane perpendicular to that point of the ridge is entirely plume-source derived. Likewise, \( \bar{P} = 0.0 \) indicates that none of the melts are plume derived, and \( 0.0 < \bar{P} < 1.0 \) indicates some of the melts are derived from the plume and some are derived from the ambient mantle material.

As shown in Fig. 15, both models 1 and 2 predict geochemical plume widths consistent with the \(-1000\)-km width inferred from the La/Sm anomaly. The largest difference between predicted and observed profiles is that the predicted profiles indicate very little mixing between the plume-derived and ambient mantle-derived melts over most of the plume-affected portions of the ridge axis. Only at the outermost \(-200\) km within the edges of the plume is there evidence for plume-ambient source mixing in our models. Similar to Ito et al.'s [1996] conclusions for Iceland, we suggest that mixing does not occur in the shallow mantle or in the crust but most likely deeper in the mantle than we have considered in our models. Such a deep mixing process may be entrainment of the ambient mantle material by the plume as it ascends through the isotopically depleted region of the mantle [e.g., Geist et al., 1988; Graham et al., 1993].

**DISCUSSION**

The above comparisons of predictions and observations at the Galápagos system as well as the scaling laws for \( W \) and \( x_{\text{max}} \) assume that the along-axis bathymetric, MBA, and
geochemical anomalies reflect directly the width of the plume in the mantle. This is likely the case if melt migration along the ridge axis is small or non-existent. If, however, along-axis melt migration is significant as suggested by Ito et al. [1996] for the Iceland-Mid-Atlantic Ridge system, then plume widths defined from geophysical or geochemical observations—which reflect largely the properties of the accumulated crust—are likely to be broader than the width of the plume in the mantle. If this is the case, then the same values of $W$ and possibly $x_{max}$ as examined here may require smaller values of $Q$ than suggested by our scaling laws. The implication for the Galápagos system is that the Galápagos plume source may be hotter and narrower than what our models imply.

Additional complexities that may affect the systematics of along-axis plume width and $x_{max}$ at plume-migrating ridge systems are ridge jumps and asymmetric plate spreading. Episodes in which the ridge jumps toward the neighboring plume has been documented for the Galápagos system [Wilson and Hey, 1995] as well as other systems in the southern ocean [Small, 1995]. Such episodes may result directly from plume-ridge interaction as the plume weakens the overlying plate near the ridge [Small, 1995]. Asymmetrically spreading ridges, which may also result directly from plume weakening of the lithosphere, are also common to plume-ridge systems [Small, 1995]. Factors such as these that affect the relative motion of the ridge are likely to have little affect on $x_{max}$ when the ridge migrates toward the hotspot because in this case $x_{max}$ is controlled by the stagnation point of the plume rather than motion of the ridge. On the other hand, ridge jumps and asymmetric spreading may increase $x_{max}$ significantly when a ridge migrates away from the hotspot because in this case $x_{max}$ is determined by the point at which the migrating ridge outruns the ridgeward spreading plume.

Regardless of how plume material is sampled by midocean ridges, our numerically derived scaling laws suggest that plumes affect broad regions of oceanic plates. In general, Eq. 14 and 15 suggest that the maximum along-axis width of a plume is 125-200% as broad as the maximum plume-ridge interaction distance. The major implication is that—as in the Atlantic and southern oceans with documented plume signatures at ridges located as far as 1400 km away—individual plumes may spread over distances of up to 2500 km perpendicular to the direction of plate motion. Such ridge-perpendicular spreading may generate broad bands of plume-affected lithosphere, which may alter otherwise normal lithosphere and contribute to characteristic properties of "tectonic corridors" such as those identified by Kane and Hayes [1992] and Hayes and Kane [1994]. Among the most prominent examples of plume affected lithosphere are the broad regions of anomalously
shallow seafloor associated with the Galápagos system as discussed in this study, the
Iceland and Azores plumes in the North Atlantic, and the Tristan plume in the south
Atlantic. Such a scenario implies that plumes are a major source of lithospheric accretion as
proposed by Morgan and Smith [1992] and Morgan et al. [1995].

CONCLUSIONS

In our numerical investigations of steady-state stationary ridges, we have derived
scaling laws consistent with those of [Ribe, 1996], indicating that they are insensitive to
differences in numerical method or model boundary conditions. Plume width \( W \) and
maximum plume ridge communication distance increase with the plume width scale
\( (Q/U)^{1/2} \) and modified plume buoyancy number \( \Pi_b \). In the case of a migrating ridge, the
distance of plume-ridge interaction is reduced when the ridge migrates toward the plume
due to the excess drag of the leading plate. After the ridge passes over and migrates away
from plume, the distance of plume-ridge interaction is enhanced due primarily to the
reduced drag of the slower-moving trailing plate, and secondarily to the pattern of thermal
erosion of the lithosphere.

To test our plume-ridge models we compare model predictions of along-isochron
mantle-Bouguer and bathymetric anomalies with observations of the Galápagos plume-
migrating ridge system. The models predict the amplitudes and widths of the observed
anomalies with a plume source temperature anomaly of 80-120°C, radius of 80-100 km,
and volume flux of \( 4.5 \times 10^6 \) km\(^3\)/m.y. The models also predict the approximate increase in
anomaly amplitudes with isochron age which reflects increased crustal production in the
past when the ridge was closer to the Galápagos plume. Crustal production rates of the
Galápagos Islands, as estimated from the observed island topography, are also matched
reasonably well by model predictions. Predictions of the geochemical signature of the
plume along the present-day ridge suggest that mixing between the plume OIB and ambient
MORB source does not occur in the asthenosphere but instead most likely occurs deeper,
possibly by entrainment of the depleted mantle as the plume ascends from its deep source
region. These numerical models suggest that plumes may spread perpendicular to the
direction of plate motion over distances 125-200% broader than the maximum distance to
which they interact with ridges. Plumes may therefore comprise a significant percentage of
the oceanic lithosphere.

Primes denote dimensionless quantities and are listed adjacent to their scaled quantities. Input parameters are $U$, $\Delta T_p$, and rheology law, which controlled $\gamma$. The remaining quantities are model output. Runs 4 and 10 had numerical box dimensions $3.2D \times 2.0D \times 1.0D$ with 128 x 64 x 50 grids in $x$, $y$, and $z$ respectively. The other runs had box dimensions $3.2D \times 1.0D \times 1.0D$ with 128 x 32 x 50 grids in $x$, $y$, and $z$ respectively. Rayleigh number was $1.83 \times 10^6$ based on $T_{\infty} = 1300$ °C and $\eta_p = 5 \times 10^{19}$ Pa s.
Figure 1. Perspective diagram illustrating steady-state flow (small arrows) and potential temperature fields (contoured at 50°C-intervals for $T > 1300^\circ C$ and 100°C intervals for $T < 1300 ^\circ C$) of an example calculation with $\Delta T_p = 100^\circ C$ and $U = 60$ km/m.y. (experiment 7, Table 2). The ridge axis is located at $x = 320$ km, the plume source is centered at $x = 450$ km. The maximum vertical velocity is 115 km/my. Both top ($z = 0$) and bottom ($z = D$) boundaries are isothermal planes with the bottom, a free slip boundary and the top, fixed at a horizontal velocity of $U/2$ (large horizontal arrow) at $x > 320$ km and $-U/2$ at $x < 320$ km. All boundaries are closed to flow both in and out of the numerical box, thus material flows downward at the ends of the box and recirculates toward the ridge axis along the base of the box. The effect of this recirculation on the interaction between plume and ridge are insignificant. Note the cooling lithosphere which slopes towards the ridge axis.
Figure 1
Figure 2. Model predictions of scaled along-axis width versus modified buoyancy number $\Pi_b\gamma$. Open circles are for runs with $\gamma = 1.0$ and temperature anomalies 100 and 200°C. Gray circles are for fully pressure- and temperature-dependent plume viscosity calculations with $\gamma = 2.35$ and $\Delta T_p = 100^\circ C$, and black circles are for temperature-dependent plume viscosity calculations with $\gamma = 5.05$ and $\Delta T_p = 200^\circ C$. The curve is the best fitting scaling law described by Eq. 6.
Figure 3. Steady state isosurface of plume tracer, \( P = 0.4 \), as viewed from the bottom of the box looking upward (shading denotes illumination from the right of the figure). Small arrows illustrate horizontal velocities in the horizontal plane at \( z = 64 \) km. The ridge axis is marked by the bold line. Experimental conditions are those of experiment 7, the same as in Fig. 1. a) \( x_p = 0 \), b) \( x_p = 100 \), c) \( x_p = 150 \). Note that the width of the plume at the ridge axis decreases with increasing \( x_p \). The maximum distance to which the plume reaches the ridge is \( x_p = 150 \).
Figure 3
Figure 4. Numerical results of along-axis plume width (scaled by width for $x_p = 0$) versus scaled plume-ridge distance. As in Fig. 2 open circles are for runs with $\gamma = 1.0$, gray circles are for $\gamma = 2.35$, black circles are for $\gamma = 5.05$. (a) The best fitting polynomials of the form given in Eq. 7 are shown for $\gamma = 1.0$ (solid), $\gamma = 2.35$ (dashed), and $\gamma = 5.05$ (dotted). The different widths of the curves illustrate the dependence of $F_2$ on $\gamma$. (b) Same as in (a) but including $F_2$ (Eq. 8) which collapses the points onto to a single curve. The standard deviation misfit of Eq 8 to the numerical results is 0.13. The mismatch to the numerical points for $x_p/(W_o F_2) \leq 1.0$ may suggest a dependence on higher order terms of $x_p$ which we chose not attempt to resolve.
Figure 4
Figure 5. Dependence of the ratio of plume volume flux crossing the ridge $Q_r$ versus scaled plume ridge distance divided by stretching function $F_2$. Symbols are the same as in Fig. 2. The solid line is the best fitting line of Eq. 9 with a standard deviation misfit of 0.08. The mismatch to the numerical points for $x_p/(W_0 F_2) \leq -0.7$ may suggest a dependence on higher order terms of $x_p$ which we chose not attempt to resolve.
Figure 5
Figure 6. Contours of lithospheric erosional thickness are normalized by characteristic plume thickness $S_o\gamma^{-1/4} = 128$ km for experiment 7 (same as Fig 3c). The ridge axis is marked by the shaded vertical line and the plume source is shown as the gray semicircle at $x_p = 150$. The thickness of the lithospheric rheological boundary layer is defined as the depths over which $\eta/\eta_o \geq 10$. Erosional thickness is the difference between the boundary-layer thickness above the plume and that of normal lithosphere as defined along the ridge-perpendicular profile at $y = 1.0D$. 
Figure 6
Figure 7. Temperature fields (contoured at 50 °C intervals in the plume and at 100°C intervals in the lithosphere) and velocities (arrows) in across-axis, depth cross-sections through the center of the plume source (y = 0). Experimental parameters are the same as in Fig 1. (experiment 7) but the ridge is migrating in the positive $x_p$-direction at the half spreading rate of 30 km/m.y. (a) Ridge is migrating toward the plume therefore the plume is beneath the faster moving Plate 1. (b) Ridge is migrating away from the plume therefore the plume is beneath the stationary Plate 2.
Figure 7
Figure 8. Numerical results of scaled along-axis width versus scaled plume-ridge distance for migrating ridge cases of experiment 7 with $U/2 = 30$ km/m.y. The bold curve as defined in Eq. 7 is that predicted for steady state conditions with a stationary ridge. Open triangles are for $V_r = 10$ km/m.y. shown with best fitting (solid) curve of the form in Eq. 11; gray triangles are for $V_r = 20$ km/m.y. shown with best fitting (dotted) curve; solid triangles are for $V_r = 30$ km/m.y. shown with best fitting (dashed) curve. Mismatches are largest near the apexes of the curves and are due in part to difficulty in resolving curvature where slope in $W$ is small, and to a possible dependence on higher order terms of $x_p$ which we chose not consider.
Figure 8
Figure 9. (a) Numerical results showing the dependence of $F_5$ on $\Pi_b \gamma$ and scaled ridge migration rate. Open circles are for runs with $\gamma = 1.0$, gray circles are for $\gamma = 2.35$, black circles are for $\gamma = 5.05$. The line is the best fitting function of Eq. 12. (b) Numerical results showing the dependence of $F_6$ on $\Pi_b \gamma$ and scaled ridge migration rate. Circles are patterned as in (a). The curve is the best fitting function of Eq. 13.
Figure 9
Figure 10. Contours of lithospheric erosion thickness normalized by characteristic plume thickness $S_o \gamma^{-1/4} = 120$ km for the migrating ridge cases of experiment 7 with $U = 30$ km/m.y. The plume source (shaded) is now at $x_p = -170$ km beneath the slower moving Plate 2. (a) The region of erosion is broadest for the case where $V_r = 10$ km/m.y. The area of erosion becomes more confined to the plume source with increasing ridge migration rates (b) $V_r = 20$ km/m.y. and (c) $V_r = 30$ km/m.y.
Figure 10
Figure 11. Map of the regional bathymetry of the Galápagos plume-ridge system (shipboard and Etopo5 bathymetry from Ito and Lin [1995a]). The present-day ridge axis is the southern-most set of white lines, and the isochrons of Ito and Lin [1995a] (taken from Wilson and Hey [1995]) are shown to the north on the Cocos Plate. The plume center is taken to be the eastern-most island Fernandina as shown by the circle of radius 100 km. The dashed box shows the region of bathymetry used to calculate the crustal volume flux of the archipelago.
Figure 11
Figure 12. Comparisons between observed (thick gray) and predicted along-isochron, bathymetric profiles from model 1 (solid) and model 2 (dashed). Model profiles are the combined isostatic topography of axial crustal thickness and mantle density variations. Maximum values of crustal thickness predicted by models 1 and 2 are labeled as $\Delta Cr_{1,2}$. 
Figure 12
Figure 13. Comparisons between observed (thick gray) and predicted along-isochron, MBA profiles from model 1 (solid) and model 2 (dashed).
Figure 13
Figure 14. Total amplitude of along-isochron (a) bathymetry and (b) MBA variations are plotted versus isochron age. Thick gray lines are observed variations, solid lines are variations predicted by model 1, and dashed lines are variations predicted by model 2. The pairs of model curves are those assuming a crustal density of 2900 kg/m$^3$ (upper-bound) and 3000 kg/m$^3$ (lower-bound) at the point of the ridge closest to the plume (91°W). (c) Crustal volume flux of the Galápagos Archipelago versus age as predicted from model 1 (solid) and model 2 (dashed) is compared with crustal volume fluxes calculated by assuming isostatic compensation of the island topography (solid gray) (see text). The upper-bound gray curve is that assuming a crustal density of 3000 kg/m$^3$ and the lower-bound curve is that assuming a crustal density of 2900 kg/m$^3$. 
Figure 14
Figure 15. Observed variations (dots) in [La/Sm]$_{ef}$ from Schilling et al. [1982] is compared with accumulated concentration of plume tracer along the ridge (Eq. 19) for model 1 (solid) and model 2 (gray).
Figure 15
CONCLUSIONS

Bathymetric and gravity observations at five prominent plume-ridge systems reveal broad wavelength anomalies that reflect anomalously low density subsurface structure imposed by the near-ridge plumes. Along-axis bathymetry shallows by as much as 4.5 km toward the plumes while along-axis mantle-Bouguer anomalies become increasingly negative by as much as -300 mGal toward the plumes. We estimate that ~70% of the anomaly amplitudes are due to thickened axial crust with the remaining ~30% due to anomalously low density mantle, both of which are caused by anomalously hot mantle temperatures imposed by the near-ridge plumes.

The amplitudes of along-isochron MBA and bathymetric anomalies are largest at the ridge-centered Iceland-Mid-Atlantic Ridge (MAR) system and at the ridge-centered cases of the Tristan-MAR system. The anomaly amplitudes decrease with increasing plume-ridge distance most likely reflecting reduced crustal production as the ridges migrated away from the plumes. At a plume-ridge distance of ~500 km the available data at the Tristan-MAR system show no discernable anomalies suggesting a maximum distance that these plumes affect ridge structure significantly. Residual bathymetric anomaly widths along the isochrons, however, appear to be most sensitive to spreading rate and decrease with increasing spreading rate from 2700 km at the slow spreading Iceland-MAR system, to < 500 km at the fast spreading Easter-EPR system.

While the above studies place constraints on the amplitude and extent of plume-imposed subsurface density anomalies, our numerical modeling studies examine the possible causes of such anomalies. Numerical models of ridge-centered plumes indicate that along-axis plume width $W$ scales with plume volume flux $Q$, ridge full spreading rate $U$, ambient/plume viscosity ratio $\gamma$, and buoyancy number $\Pi_b$ according to $W = 2.37(Q/U)^{1/2}(\Pi_b \gamma_r)^{0.04}$. Thermal buoyancy is the most important driving force while melting effects of latent heat loss, depletion buoyancy, and melt-retention buoyancy yield competing effects which do not change the above scaling argument. Numerical simulations of the Iceland-MAR system suggest two end-member source models. The first model has a source radius of 300 km, temperature anomaly of 75°C, and volume flux of $1.2 \times 10^7$ km$^3$/m.y., while the second has a source radius of 60 km, temperature anomaly of 170°C, and volume flux of $2.1 \times 10^6$ km$^3$/m.y. The first model explains well the observed crustal thickness, bathymetric, and MBA variations along the MAR and Iceland, but the second model requires substantial along-axis melt transport in order to explain the observations.
This second model may be more representative of the Iceland plume based on similarities between predicted and observed mantle P-wave anomalies.

For off-axis plumes, along-axis width scales again with \((Q/U)^{1/2}\) and \(\Pi_b \gamma\); in a similar manner to the ridge-centered plume case. For steady-state plumes near stationary midocean ridges, \(W\) decreases with increasing plume-ridge distance and becomes zero at a maximum plume-ridge interaction distance \(x_{max}\), which increases with \((Q/U)^{1/2}\) and \(\Pi_b \gamma\). When ridges migrate toward plumes, however, predicted values of \(W\) and \(x_{max}\) are reduced relative to the case of a stationary ridge by as \(-24\%\) due to the enhanced drag of the overlying plate that leads the migrating ridge. On the other hand, when ridges migrate away from plumes, \(W\) and \(x_{max}\) are predicted to increase by \(-36\%\) due to reduced drag of the trailing plate; enhanced erosion of the lithosphere also enhances \(W\) and \(x_{max}\) but to a degree that is secondary to the effects of reduced plate shearing. Numerical models of the Galápagos plume-ridge system predict MBA and bathymetric anomalies that match successfully the amplitudes and widths of the observed anomalies, as well as the increase in anomaly amplitude with isochron age. The implied Galápagos plume source has of radius 80-100 km and temperature anomaly of 80–120°C. In addition, predicted chemical signatures of the plume along the model ridge suggest that mixing between the plume and ambient mantle occurs deeper than the asthenosphere, most likely due to entrainment of the ambient mantle as the plume ascends from its deep source reservoir.

Thus for a few prominent plume-ridge systems, we have begun to quantify the influence of near-ridge plumes on ridge crustal and mantle density structure. The suggestion that subsurface structure along seafloor isochrons reflects past interaction between plumes and ridges warrants further investigations to test, in the form of land-based data analyses as well as sea going geophysical and geochemical surveys. In addition, we have learned a great deal about how mantle flow might behave at plume-ridge systems. Our models also require further studies to test, most likely with mantle seismological studies. Finally, as we have discussed for the Iceland-MAR system, along-axis melt transport may be a first-order process for this and possibly other plume-ridge systems. If this is the case, it may be time to re-examine our established ideas of plume-ridge interaction and possibly crustal accretionary processes at ridges in general.
APPENDIX

LABORATORY INVESTIGATION OF THE INTERACTION OF OFF-AXIS MANTLE PLUMES AND SPREADING CENTRES
Laboratory investigation of the interaction of off-axis mantle plumes and spreading centres

C. Kincaid*, G. Ito† & C. Gable‡

Mantle plumes and mid-ocean ridge spreading centres are the dominant phenomena through which mass and heat are transported from the mantle to the Earth's surface. It now seems that the feasibility of this model with laboratory experiments that incorporate the essential physical and fluid dynamic aspects of a plume–ridge upper mantle system. Our results indicate that an off-axis plume may communicate thermally and chemically with a spreading ridge through a narrow, sub-horizontal conduit instead of a broader, radially spreading plume head. A necessary condition for this communication is the presence of a lithospheric or rheological boundary layer that thickens away from the ridge axis owing to conductive cooling. Interestingly, we find that for high plume temperatures, increasing the plume thermal buoyancy may inhibit rather than enhance plume–ridge interaction, as a result of increased erosion of the overlying lithosphere.

Recent laboratory and numerical experiments have considered the dynamics of plume–ridge interaction for the ridge-centred case; however, the difficult question remains as to how a plume and a ridge interact thermally, chemically and dynamically when the plume is located off-axis. A model of sub-horizontal pipe-like flow from the off-axis plume to a ridge axis along the base of the rigid lithosphere has been suggested (Fig. 1a).

Geochemical studies and two-dimensional numerical experiments support this channel-flow model and suggest that geochemical communication may persist over long periods of time and plume–ridge separation distances as high as 1,200 km (ref. 16). This laboratory experimental project is the first fully three-dimensional numerical investigation of plume–ridge interaction and its effects on the dynamics of plume–ridge interaction for the ridge-centred case; however, the difficult question remains as to how a plume and a ridge interact thermally, chemically and dynamically when the plume is located off-axis. A model of sub-horizontal pipe-like flow from the off-axis plume to a ridge axis along the base of the rigid lithosphere has been suggested (Fig. 1a).

Geochemical studies and two-dimensional numerical experiments support this channel-flow model and suggest that geochemical communication may persist over long periods of time and plume–ridge separation distances as high as 1,200 km (ref. 16). This laboratory experimental project is the first fully three-dimensional numerical investigation of plume–ridge interaction and its effects on the dynamics of plume–ridge interaction for the ridge-centred case; however, the difficult question remains as to how a plume and a ridge interact thermally, chemically and dynamically when the plume is located off-axis.
dimensional variable-viscosity study of this problem, and it exposes the mechanisms by which an off-axis plume overcomes the lithospheric drag that draws material away from a ridge, to successfully feed the nearby spreading centre.

To test the conceptual model of plume–ridge channeling (Fig. 1a), we simulate a ridge–ridge, upper mantle system with a tank of a concentrated sucrose solution which, like the Earth’s mantle, is strongly temperature dependent (Fig. 1b). Plate-driven mantle flow is simulated by dragging two Mylar sheets in opposite directions on the surface of the fluid at a constant rate of 0.35 cm min\(^{-1}\) \((U_s\), half-spread rate). Buoyantly driven flow is produced through a supply of thermal energy from a disc-shaped resistance heater (that is, the plume source) positioned at the base of the tank. The two parameters we vary are the surface temperature, thus the thickness/age of the upper rheological boundary layer (RBL), and the plume source temperature, controlling the strength of the rising plume. Fluid temperature is continuously monitored at the disc heater, at the surface of the Mylar, along a vertical profile within the fluid, and along the ridge axis with resistance temperature detectors (RTDs) (Fig. 1c).

Plume buoyancy is caused by density reduction of the plume fluid due to thermal expansion according to

\[
\Delta \rho = (\rho_0 - \rho_p) = a \rho_p (T_p - T_s)
\]

where \(a\) is the expansion coefficient \(4.6 \times 10^{-5}\), and \(\rho_p\), \(T_p\) and \(\rho_s\), \(T_s\) are reference and plume densities and temperatures,

*Calculated as a ratio of plume buoyancy flux at the ridge, \(B_p = \rho_pU_pD_{ri} \left[(T_r) - (T_s)\right] dx\), where the x axis is along the ridge, \(D_{ri}\) is mean RBL thickness and \(T_r\) is along-axis temperature, and plume source buoyancy flux, \(B_p = \rho_pU_pD_{ri}d(2\rho)/(\Delta \rho)\), where \(U_p\) is bead velocity within the plume conduit and \(d\) is conduit diameter (1.5–1.8 cm). \(B_p\) ranges between 0.003–0.004 g s\(^{-1}\). Reference density, \(\rho_p\), at ambient temperature (20 °C) is 1.4 g cm\(^{-3}\). Important parameters for comparing results on \(B_p/\mu_p\) are highlighted in bold. Comparisons are also made using plume Peclet number, \(P_e_b/\mu_p\), and the ratio \(P_e_b/\mu_p\). Mantle \(P_e_b\) is calculated from Whitehead and Luther's\(^{15}\) equation for \(U_p\), \(B_p\), \(P_e_b\), and \(P_e_b/\mu_p\). Which best represent the vigour of plume convection relative to plate-driven flow, and \(\mu_p/\mu_s\) scale well with expected mantle values, \(\mu_p/\mu_s\) and \(\Delta \rho/\rho_p\) reflect differences in laboratory and mantle material properties.
FIG. 3a. Photograph of the tank fluid during experiment 2 showing locations of 7 Delrin beads (trajectories sketched in black). Bead no. 1 reached the high-viscosity upper boundary layer then travelled along a sub-horizontal path to the ridge axis similar to the depiction in Fig. 1a. This photograph was taken 05 min after plume initiation, 50 min after the plume–RBL impact, and 15 min after bead no. 1 hit the ridge. The bead is now frozen into the migrating plate. The photograph was taken 65 min after plume initiation, 50 min after the plume-RBL impact, and 15 min after bead no. 1 hit the ridge. The bead is now frozen into the migrating plate. The photograph is taken from a mid-depth fluid level, and the dark sloping line is the ridge axis (line of RTDs) as viewed from below, through the fluid. The bead below and to the left of no. 7 was introduced while setting the bead source and is not part of the experiment. Bead no. 1's arrival. This photograph was taken 65 min after plume initiation, 50 min after the plume-RBL impact, and 15 min after bead no. 1 hit the ridge. The bead is now frozen into the migrating plate. The photograph is taken from a mid-depth fluid level, and the dark sloping line is the ridge axis (line of RTDs) as viewed from below, through the fluid. The bead below and to the left of no. 7 was introduced while setting the bead source and is not part of the experiment. Bead no. 1's arrival. Fluid temperatures measured by eight RTDs along the ridge axis at different times during experiment 2, showing evolution of a narrow axial anomaly. Temperatures increase with time primarily at RTD 5, peaking at ~3 °C above ambient temperature. Temperatures are still increasing at 95 min, or 45 min beyond bead no. 1's arrival. Fluid temperatures along the ridge axis at the conclusions of the four experiments. Without the RBL (experiment 1) or if the plume is too hot (experiment 4), the plume fails to reach the ridge and enhance ridge temperatures. Note the broader axial anomaly for the case with a larger (3') RBL slope (experiment 3).

Length and time scales in the laboratory models are related to the mantle through the Péclet number,

\[ Pe = \frac{U}{D_\kappa} \]

Thermal diffusivity, \( \kappa \), of the laboratory fluid is 0.001 cm\(^2\) s\(^{-1}\) and the corresponding mantle value is 0.01 cm\(^2\) s\(^{-1}\). We define the length scale, \( D \), as the thickness of the laboratory fluid (17 cm) corresponding to 600 km of the upper mantle. Thus, our 0.35 cm min\(^{-1}\) Mylar speed yields \( Pe = 100 \) and scales to a slow mantle full-spreading rate of ~1 cm yr\(^{-1}\). Likewise, our laboratory plume–ridge separation distance of 14 cm scales to a mantle distance of ~500 km.

The four experiments we present here are selected from a total of nine to highlight the relative roles of surface cooling (compare experiment 1 with 2, and 2 with 3) and plume source temperature respectively. We characterize the strength of the plume by the dimensionless buoyancy number, \( B_\alpha \), defined as

\[ B_\alpha = \left( \frac{\rho g q Q}{\mu v U^2} \right) \]

where \( g \) is the acceleration due to gravity, \( \mu \) is reference dynamic viscosity and \( Q \) is the volumetric plume flux\(^\text{v} \), which is a constant 0.15 cm\(^2\) s\(^{-1}\) between experiments. Characterizing plumes in this manner enables us to compare plumes quantitatively between experiments (see Table 1) and provides a measure of how well our laboratory plumes represent Earth examples. Our laboratory \( B_\alpha \) are near the upper limit of the expected range for the Earth of 7–59 (ref. 8).
LETTERS TO NATURE

(compare experiments 2 and 4) on plume-ridge communication (see Table 1). In experiment 1 (Fig. 2), the fluid surface is not cooled, but rather maintained at room temperature: therefore no sloping RBL is present. As the rising plume reaches the surface, the plume head flattens and widens (10-12 cm wide), but we see that without a sloping RBL the plume is strongly deflected away from the spreading axis such that no plume material reaches the ridge (Fig. 2c).

Experiment 2 is performed with the same plume source temperature but with surface cooling, which, combined with plate spreading, induces a characteristic upper thermal/rheological boundary layer that slopes towards the spreading axis. If we arbitrarily define the RBL as the isosurface along which viscosity is twice that of the ambient fluid (175 Pa s⁻¹) then the RBL thickness above the plume source is 0.25 cm (that is, 350 Pa s at 15.5°C) after the plate-driven flow has established. The initial RBL slope in this experiment is then 1°, assuming zero RBL thickness at the ridge axis 14 cm away.

The role of the RBL on plume-ridge interaction is apparent in the paths of neutrally buoyant tracer beads (Fig. 3a). Most beads plate-floated by the plate flow, but two (1 and 2 in Fig. 3a) migrate toward the ridge, indicating successful plume-ridge communication. The bead source is positioned on the side of the plume heater, away from the ridge axis. Because of this, and the fact that only a small percentage of the plume is channelled to the ridge, a large number of beads (3-7) track the fraction of plume being deflected from the ridge. Long-term sampling of plume material by the ridge is more clearly recorded by the axial temperatures, which increase steadily with time as hotter plume material reaches the ridge (Fig. 3b). This plot shows axial temperatures still increasing at 95 min, which is 45 min (or 55 Myr) beyond the arrival of bead 1 at the ridge. Spatially, the temperature anomaly is centred on RTD 5 with an axial width of roughly 10 cm (350 km). This narrow, confined axial anomaly indicates that plume flow alo x the sloping RBL, the off-axis plume is channelled ridgeward through a narrow conduit as predicted from constructional volcanism and geochemical studies. The scaled anomaly width of roughly 350 km is the approximate width of geographical anomalies along the Mid-Atlantic Ridge (MAR) associated with the Ascension and Tristan hotspots, both of which are ~400 km from the MAR, similar to scaled laboratory plume-ridge offsets of 350 km.

Also consistent with the behaviour of the Tristan system is the substantial cooling of the laboratory plume as it migrates from the source to the ridge. The laboratory plume source temperature is 35-40°C higher than the ambient temperature. The equivalent mantle plume temperature excess is ~500°C using a mantle a value of 3 x 10⁻², but at the ridge the temperature anomaly is only ~3°C or a mantle equivalent of 45°C, indicating that substantial conductive cooling of plume material occurs between the source and ridge axis. Most cooling probably occurs along the sub-horizontal plume conduit (path A-B in Fig. 1a) where bead velocities drop to 0.5-1 cm min⁻¹ and the plume is in direct contact with the cold upper boundary layer. Analogously, the Tristan plume is expected to have cooled by as much as 200°C along its migration path to the MAR.

In experiment 3, the surface is cooled even further to yield an initial RBL slope of ~3° between the plume and ridge. Here the resulting axial temperature anomaly is broader (~20 cm or 700 km) than with the 1° slope (Fig. 3c). Assuming that the axial anomaly reflects directly the plume flux to the ridge, we estimate that the ridgward plume buoyancy flux (see Table 1) is ~10% of the entire source flux, or ~3 times that estimated for experiment 2, where RBL slope was a third as large. These results suggest that the proportion of a plume that feeds a nearby ridge depends directly on the amplitude of the RBL slope, which is consistent with results from two-dimensional numerical experiments. Because the lithosphere probably slopes by 3°-10°, even larger proportions of plumes may feed ridges in the mantle.

Finally, experiment 4 is identical to experiment 2, except with a 20% higher plume-ambient-temperature contrast. Although intuitively it might seem that increasing plume buoyancy should increase plume flow along the sloping RBL to the ridge, the absence of any plume signal at the ridge for this stronger plume case (Fig. 3c) indicates that this relationship does not necessarily hold. Instead, the hotter plume erodes a pocket in the RBL (Fig. 1a) which traps the plume head in the translating viscous state, a result consistent with two-dimensional numerical experiments (C.K., J.-G. Schilling and C.G., manuscript submitted). The trailing conduit is tilted away from the ridge, thereby prohibiting further ridgward flow. Such behaviour may, in part, explain why only the weakest plumes discussed by Sleep² have recognizable signatures at nearby ridges. The most robust present-day plume is Hawaii, but it is located >5,000 km from the nearest ridge. The prediction from these experimental results is that lithospheric erosion may have prohibited communication of the Hawaiian plume with the East Pacific Rise throughout its existence, even during 50-70 Myr ago when it was closer to the ridge than it is today.

Our fully three-dimensional variable-velocity laboratory experiments indicate that the preservation of an upper rheological boundary that thins toward the ridge axis is the primary requirement for communication between an off-axis mantle plume and a nearby spreading centre. The greater the RBL slope, the more effectively it diverts the buoyant low-velocity plume material to the ridge. But extremely hot plumes may erode the RBL thus precluding the plume from feeding the ridge. Our laboratory results show that the plume signal at the ridge is narrow, indicating that communication could be through a confined conduit such as has been proposed as a result of previous observations¹⁵. Continuing laboratory experiments are investigating the effects of larger RBL slopes and wider ranges in plume buoyancies and plate velocities on plume-ridge dynamics. It is important to note that in cases where ridges have migrated away from ridge-centred plumes, the dynamics of interaction may be affected by the track of this lithosphere (e.g. thermal groove) that is left behind. To address this issue, the laboratory apparatus is also being employed in a study of stationary plumes interacting with migrating ridges and plumes beneath ridge-transform offsets.
