1 **Abstract**

2

3 Sound is a widely available cue in aquatic environments and is used by many marine
4 animals for vital behaviors. Most research has focused on marine vertebrates.

5 Relatively little is known about sound detection in marine invertebrates despite their

6 abundance and importance in marine environments. Cephalopods are a key taxon in

7 many ecosystems but their behavioral interactions relative to acoustic stimuli have

8 seldom been studied. Here we review current knowledge regarding (i) frequency

9 ranges and sound levels that generate behavioral responses, (ii) the types of

10 behavioral responses and their biological relevance.

11

12 **1. Introduction**

13

14 Sounds are abundant in the ocean. They are produced by a range of organisms

15 (e.g., fish, crustaceans, mammals, etc.) and by abiotic conditions (e.g., wind, waves,

16 rain, earthquakes, etc.). Underwater sounds travel relatively fast ($\sim 1500 \text{ m}\cdot\text{s}^{-1}$), can be

17 detected over long distances (Urick 1983), and are often available when sensory cues

18 such as light or chemical stimuli may be limited (Popper & Hastings, 2009). It is well

19 established that many marine vertebrates detect and use sound for vital activities such

20 as navigation, foraging, predator detection and reproduction (Fay & Popper, 1999; Au

21 et al., 2000). The ability of marine invertebrates to detect and potentially use sound is

22 far less understood, which is somewhat surprising given their relative abundance and

23 central role in many aquatic ecosystems (Budelmann, 1992a, b; Boyle & Rodhouse,

24 2005).

25 Sound detection in cephalopods was first reported by Baglioni (1910), who

1 noted that octopuses reacted to low-frequency acoustic vibrations and water
2 movements. Later publications included the description of behavioral (Dijkgraaf,
3 1963; Komak et al., 2005), physiological (Kaifu et al., 2007), conditioned (Packard et
4 al., 1990), and neurological responses (Hu et al., 2009; Mooney et al., 2010) to sound
5 stimuli of different frequencies and intensities.

6 The organs generally thought to enable sound detection in cephalopods are the
7 statocysts (Hanlon & Messenger, 1996; Kaifu et al., 2008). These are paired organs
8 located in the cartilage below the brain. They consist of a fluid-filled cavity
9 containing a macula-statolith system for the detection linear acceleration (e.g.,
10 gravity) and a crista-cupula system for the detection of angular acceleration (e.g.,
11 movement) (Budelmann, 1975). Polarized hair cells are found in both the maculae and
12 the cristae systems (Budelmann, 1979). The component of a sound field likely
13 perceived by cephalopods is particle acceleration, not sound pressure (Packard et al.,
14 1990; Mooney et al., 2010). In addition to the statocysts, *Sepia officinalis* (European
15 common cuttlefish) also has lines of epidermal hair cells, running over the head and
16 arms, that detect local water displacement (Budelmann et al., 1991; Hanlon &
17 Messenger, 1996). Their contribution to sound detection is poorly understood.

18 In the past decades, the development and greater use of the ocean have led to a
19 concurrent increase in anthropogenic noise (National Research Council, 2005). This
20 noise may stem from many sources including shipping and vessel traffic, sonar
21 systems, seismic air guns, and oil drilling. Our increased awareness of the influences
22 of anthropogenic noise on the marine environment has led to several scientific studies
23 addressing its potential impacts on diverse marine life (e.g. Mooney et al., 2009;
24 André et al., 2011; Fewtrell & McCauley, 2012). (André et al. 2011)

25 Cephalopods play an important role in ecosystems and are a key component of

1 food webs, providing a vital link from smaller invertebrates and fish to marine
2 megafauna, birds, and humans (Boyle & Rodhouse, 2005). It is therefore important to
3 investigate the potential impact of increased anthropogenic noise on cephalopods.
4 Changes in the behavior and distribution of cephalopod populations could have
5 substantial impacts on the survival and distribution of top predators such as marine
6 mammal, sharks, and sea birds; such changes would also impact commercial fisheries
7 (Boyle & Rodhouse, 2005). In this paper, we review research regarding cephalopod
8 behavioral responses to sound, placing these studies in the context of potential noise
9 impacts. In particular, we address the frequency and sound level ranges that generate
10 behavioral responses in cephalopods, the types of behavioral responses elicited and
11 their biological relevance,

12

13 **2. Behavioral responses to various acoustic stimuli**

14

15 Cephalopods have a broad behavioral repertoire, including body movements
16 (arms, mantle), body pattern changes, locomotor responses (jetting, fin movements)
17 and inking (Hanlon & Messenger, 1996). Multiple ethograms have been published
18 (e.g. Hanlon & Messenger, 1988; Hanlon et al., 1999 and references therein) and
19 these provide the framework for future experiments in which behavioral responses to
20 acoustic stimuli can be observed, recognized, and categorized in a quantitative
21 manner.

22 Figure 1 summarizes cephalopod responses to sound. Dijkgraaf (1963)
23 reported jetting, darkening of the skin, and narrowing of the pupils in *S. officinalis* in
24 response to taps on the tank walls. Body patterning changes were observed when
25 using 180 Hz tones. Juvenile cuttlefish exhibited changes in body patterning,

1 displacements, and burrowing when exposed to local sinusoidal water motion from 20
2 – 600 Hz (Komak et al., 2005). Certain frequencies generated substantially higher
3 levels of activity in juvenile animals. Unfortunately, the stimuli intensities (measured
4 as sound pressure level or particle motion) were not reported. Recently, using acoustic
5 stimuli ranging from 80 – 1000 Hz and a range of sound levels (measured in both
6 sound pressure and particle acceleration), Samson et al. (this conference, in prep)
7 categorized the behavioral responses of *S. officinalis* to different tones. The responses
8 included fin movements, body pattern changes, startle, jetting, and inking. Reactions
9 considered to be escape and/or startle behavior (blanching, jetting, inking) mostly
10 occurred at low frequencies and high sound levels. The average sound level needed to
11 elicit a certain response varied for each sound frequency.

12 Similar escape responses have been observed in squid *Sepiotheutis australis*
13 exposed to seismic air gun noises. The animals showed inking and jetting behaviors,
14 increased swimming speed, and swam upward, possibly to benefit from the sound
15 shadow near the water surface (McCauley et al., 2000; Fewtrell & McCauley, 2012).
16 In *Octopus ocellatus*, Kaifu et al. (2008) reported changes in respiratory rates during
17 exposure to sounds 50 – 283 Hz. Although octopuses are also capable of body pattern
18 changes, jetting, and inking, those behaviors were not mentioned in the literature as
19 responses to sound stimuli.

20

21 **3. Potential for habituation to acoustic stimuli**

22

23 Studies on the potential for habituation of cephalopods to any kind of stimulus
24 are scarce; most research on the learning capabilities of these animals has focused on
25 memory and spatial learning (e.g. Karson et al., 2003; Agin et al., 2006). Visual

1 habituation to a predator model has been observed in the squid *Lolliguncula brevis*
2 (Long et al., 1989); the squids showed a decrease in body pattern changes and jetting
3 with repeated presentation of the fish models. Visual and tactile habituation were also
4 demonstrated in *Octopus vulgaris*; animals showed long-term habituation to visual
5 stimulation using a prey model, and a decrease in object handling over time (Kuba et
6 al. 2006).

7 Cephalopod habituation to acoustic stimuli has yet to be addressed in detail.
8 Only a few notes on the subject, collected *en passant* during previous studies on
9 sound detection in cephalopods, have been found in the scientific literature. Dijkgraaf
10 (1963) mentioned a very quick habituation to a 180 Hz tone in *S. officinalis*; after only
11 one exposure, the animals would not react to the stimulus anymore. Using juvenile *S.*
12 *officinalis*, Komak et al. (2005) obtained opposite results: no habituation was
13 observed to repeated stimuli of different frequencies ranging from 40 – 600 Hz.

14 Following behavioral tests to different sound frequencies and levels, Samson
15 et al. (this conference, in prep) exposed *S. officinalis* to repeated sound exposure at
16 200 Hz and at different sound levels. A potential for habituation was observed;
17 response intensity decreased but response extinction was not reached within the time
18 of the experiments.

19

20 **4. Future research directions**

21

22 Studying behavioral responses in corroboration with physiological,
23 conditioned, or neural responses is a productive way forward to determine the
24 function of sound in cephalopod life history. Physiological responses, for example,
25 can provide information on detection ranges and thresholds (Hu et al., 2009; Mooney

1 et al., 2010), but not on the use of sound by organisms and the role it plays in vital
2 behaviors such as feeding, defense or reproduction. Behavioral responses may also
3 reveal cephalopod functional use of sound stimuli. Moreover, knowing how animals
4 respond to sound is important from an ecological point of view (Hanlon & Shashar,
5 2003) and should enable us to predict disruptive effects of anthropogenic sounds on
6 population behaviors (e.g., migration, spawning) and ecosystems, as there is a
7 substantial overlap among the hearing ranges of many key organisms and the ranges
8 of anthropogenic noise in the ocean (Figure 2). It is unclear which type of acoustic
9 information influences cephalopod ecology, given the low frequencies they react to,
10 and the absence of behavioral responses to ultrasonic clicks typical of odontocetes, a
11 prominent group of cephalopod predators (Wilson et al., 2007).

12 Microscopic studies have shown that the hair cells in the statocysts and
13 epidermal lines of *S. officinalis* and other cephalopods are polarized (Budelmann,
14 1979; Budelmann et al., 1991). This characteristic of the hair cells could be the
15 anatomical basis for directional hearing and sound location in cephalopods. The
16 ability to sense the direction of acoustic stimuli and the location of acoustic sources
17 has likely functions in defense but could also play roles in other behaviors including
18 navigation. Investigating these potentials in cephalopods might shed light on
19 important aspects of their sensory ecology.
